EDITOR-IN-CHIEF

Nima Rezaei gained his medical degree (MD) from Tehran University of Medical Sciences and subsequently obtained an MSc in molecular and genetic medicine and a PhD in clinical immunology and human genetics from the University of Sheffield, UK. He also spent a short-term fellowship of pediatric clinical immunology and bone marrow transplantation in the Newcastle General Hospital. Professor Rezaei is now the full professor of immunology and vice dean of International Affairs, School of Medicine, Tehran University of Medical Sciences, and the co-founder and head of the Research Center for Immunodeficiencies. He is also the founding president of Universal Scientific Education and Research Network (USERN). Prof. Rezaei has already been the director of more than 100 research projects and has designed and participated in several international collaborative projects. Prof. Rezaei is the editor, editorial assistant, or editorial board member of more than 40 international journals. He has edited more than 50 international books, has presented more than 500 lectures/posters in congresses/meetings, and has published more than 1100 scientific papers in the international journals.

EDITORIAL BOARD

Editor-in-Chief

Nima Rezaei

Research Center for Immunodeficiencies, Children's Medical Center, Tehran University of Medical Sciences, Tehran, Iran; Department of Immunology, School of Medicine, Tehran University of Medical Sciences, Tehran, Iran; Network of Immunity in Infection, Malignancy and Autoimmunity (NIIMA), Universal Scientific Education and Research Network (USERN), Stockholm, Sweden

Section Editors

Section 1. The Immune System

FOREWORD

It is a great honor to be asked to introduce, with this foreword, the *Encyclopedia of Infection and Immunity*. This work will be read and enjoyed by many students, both graduate and postgraduate, including clinicians, laboratory practitioners, and scientists. Many colleagues have contributed to this important work, with over 230 original chapters assembled in sections and listed alphabetically. I offer my warm congratulations to the editors of this book, for soliciting a wide body of expertise and assembling it in a form that gives so much pleasure and information to the reader.

For those of us who work in the field of infection and immunity, the last two years have been exceptionally challenging. At the current time we are 22 months into a major pandemic caused by a novel coronavirus and its variants, and worldwide, sadly, there have been many hospitalizations and deaths. Clinicians and scientists in our field have been working flat out, caring for patients, generating or utilizing diagnostic tests, generating new knowledge in immunity to coronaviruses, or discovering, testing, and deploying new vaccines. Public Health practitioners have organized our medico-social responses to limit transmission and deal with the consequences of infection. Behavioral scientists have transformed our approach to informing the public, getting the best possible outcomes from effective communication. Governments have learned the danger of ignoring the expertise of scientists, and in many countries, the public look upon clinicians and scientists with gratitude and respect. It is a testament to the advancement of infection and immunity science that the genome of the virus was sequenced within a few weeks of COVID-19 emerging, and that within 12 months, the first trials of novel vaccines had been completed. These vaccines included some with exceptionally novel technologies, including the RNA vaccines and the viral-vectored vaccines.

Underpinning the academic agility of students and practitioners in Infection and Immunity is the universal strength of sound education. Readers of this book will be seeking the knowledge they need for a comprehensive understanding of infectious disease and immunology. We work in a fascinating discipline. Our field is unique in that pathogenesis involves at least two sets of genomes—on the one hand the microbe, and on the other, the host. The microbial genome programs its microenvironment to enable acquisition of and residence in a niche for sufficient time to replicate and further disseminate to other hosts. The human genome has evolved to tolerate and contain a wide range of symbionts and pathobionts, with highly sophisticated immune decision-making at the cellular level, but to respond to invading species with an elaborate coordinated repertoire of innate and acquired immunity. The complex conversation between many different microbes and the human host generates a wide range of disease phenotypes. This makes the job of an infectious disease physician so challenging but at the same time so fulfilling.

Our field is enriched by the many scientists and clinicians who are willing to share their experience with their peers and students. This book reflects the great variety of knowledge that has emerged over centuries of inquiry and endeavor, and I believe you will be rewarded by using it as one of your reference sources.

Robert C. Read

Editor-in-Chief, Journal of Infection

Professor of Infectious Diseases and Consultant Physician

University Hospital Southampton, United Kingdom

PREFACE

Although infections have been one of the most important health threats since centuries ago, the mechanisms of human defense against infections have been unclear until last century. The scientific world has remarkable progresses in the field of immunology during recent decades. Indeed, the novel discovery of genes related to different pathogens has enhanced our knowledge about the immune system. Understanding different pathogens and the immune mechanisms promote diagnostic strategies and design more efficient therapeutic agents.

Encyclopedia of Infection and Immunity is a comprehensive text, which covers topics not only on basic immunology and microbiology but also on clinical immunology and infectious diseases. Section 1 focuses on the immune system, while Section 2 describes the interaction between pathogens and immunity. Bacteria, viruses, fungi, protozoan parasites and helminths, and insect and mites are explained in Sections 3–6, respectively. Section 7 discusses the clinical infectious disease challenges, whereas clinical immunology is covered in Section 8. Laboratory tests and treatment protocols are the main focuses of Sections 9 and 10, respectively.

Encyclopedia of Infection and Immunity is the result of valuable contribution of more than 400 scientists from many well-known universities/institutes worldwide. I would like to hereby acknowledge the expertise of all contributors, for generously devoting their time and considerable effort in preparing their respective chapters. I would also like to express my gratitude to Elsevier for providing us the opportunity to publish this Encyclopedia.

Finally, I hope that this comprehensive book will be of special value for researchers and clinicians who wish to extend their knowledge on infection and immunity.

Nima Rezaei, MD, PhD

CONTENTS OF VOLUME 1

Section 1: The Immune System, Edited by Nima Rezaei

General Concepts of Immunity	1
<i>Nima Rezaei, Mona Sadeghalvad, and Hamid-Reza Mohammadi-Motlagh</i>	
Organs and Tissues of the Immune System	14
<i>Hamid-Reza Mohammadi-Motlagh, Mona Sadeghalvad, and Nima Rezaei</i>	
Structure and Function of the Immune System	24
<i>Mona Sadeghalvad, Hamid-Reza Mohammadi-Motlagh, and Nima Rezaei</i>	
Adaptive Immunity	39
<i>Hamid Reza Mirzaei</i>	
Cell-Mediated Immunity	56
<i>Samira Rajaei</i>	
T Cell Development	64
<i>Joshua DeSousa Casal and Juan Carlos Zúñiga-Pflücker</i>

Introduction to immune system

Maintaining homeostasis in response to environmental alterations is a significant challenge for living organisms. Elimination of invading pathogens and damaged or harmful cellular contents is an inevitable challenge that all organisms have to contend with it. The body's defense against the potential dangers and re-establish homeostasis rely on "immune system" which consists of the cells and molecules responsible for protecting the host body from harmful agents. In this way, the comprehensive and organized response of immune system components leads to the formation of an "immune response." Although an ideal immune response would eradicate the imminent danger and restore homeostasis to affected tissues, its improper activity can also be detrimental and cause tissue damage. Hence, the regulation of immune responses is crucial, allowing the organism to modulate the intensity and duration of the responses (Chaplin, 2010).

To provoke an efficient response, the immune system must recognize a wide range of infectious agents named pathogens such as viruses, bacteria, parasites, and fungi and discriminate them from the host's own tissues. This process is performed by a variety of receptors expressed on the immune cells (Medzhitov and Janeway, 1998). Any substances recognized by immune system components named "Antigen" and the specific part of an antigen recognized by immune receptors is called "Epitope." One of the unique features of the immune system is the ability to distinguish between "self" and "non-self" antigens. To prevent inappropriate reactions, the immune system must have tolerance against host's own molecules. This is an important event which states the concept of "immune tolerance" theory. Disruption of self-tolerance or inappropriate regulation of immune responses could lead to immune reaction to host cellular components resulting in a state known as "autoimmunity" (Chaplin, 2010).

In overall, immune system can be categorized into two types include “innate” and “adaptive” immunity. The innate immune system is the first line of defense which quickly activated against pathogens. This type of immune response reacts in the same way to all foreign antigens, which is why it is named as the “non-specific” immunity. However, an efficient immune response requires the involvement of adaptive immunity. The adaptive immune system specifically recognizes the antigens and responds slower than innate immune system. The advantage of adaptive immunity is the production of “memory” cells which can react immediately against pathogens. Therefore, when a known antigen is encountered for second time, the adaptive immune system can react faster (McCullough and Summerfield, 2005). In this article, we aimed to describe the basic concepts of immune system including the important components of innate immunity and adaptive immunity as well as the basic effective mechanisms in order to pathogen elimination.

Innate immunity: The first line of defense against pathogens

As an old evolutionary defense mechanism, the innate immune system or native immunity, provide the first line of defense against pathogens. Innate immunity is responsible for respond immediately (within minutes) to microbial components and harmful agents caused by cellular stress or tissue damage. Innate immune system consists of the cellular and biochemical components that are present active even before infection. Although some of them including complement system and cellular compartments become active upon danger exposure. An important feature of the innate immune system is its ability to activate the adaptive immune system (Tosi, 2005; Beutler, 2004).

Innate immune response provides the immunity against pathogens through several ways including:

1. Pathogens blocking from entering the body.
2. Pathogen uptake by phagocytosis or pinocytosis.
3. Pathogen killing via cytotoxic mediators.
4. Increased recruitment of the other immune cells by production of inflammatory mediators.
5. Pathogen processing and antigen presentation to adaptive immune cells.

Effector mechanisms of innate immune response

Recognition of conserved molecular patterns of pathogens

Innate immune response relies on the recognition of molecular patterns existed on the pathogens or damaged associated molecules which produced during injury, infection, or disease condition. These molecular patterns are including “pathogen-associated molecular patterns” (PAMP) such as lipopolysaccharide (LPS) of Gram-negative bacteria, peptidoglycan of bacterial cell wall, and viral RNA; and “damaged-associated molecular patterns” (DAMP) such as heat shock proteins (HSPs) and high mobility group box 1 (HMGB1). PAMPs or DAMPs could be recognized by non-specific receptors named “pattern recognition receptors” or PRRs expressed on immune system components. Several types of PRRs including Toll-like receptors (TLR), nucleotide-binding oligomerization domain (NOD)-Leucine Rich Repeats-containing receptors (NLR), retinoic acid-inducible gene 1 (RIG-1)-like receptors (RLR), and the C-type lectin receptors (CLRs) have been identified which are differently diffused in sub cellular compartments such as cytosol, cell membrane, and endosomal membrane. Ligand-induced activation of PRRs initiates inflammatory responses resulting in the promotion of pathogen elimination as well as tissue homeostasis (Mogensen, 2009).

Phagocytosis: A killing mechanism by phagocytes

Phagocytes are the major innate immune cells act as the first line of defense against microorganisms. The important phagocytes are monocytes and macrophages, neutrophils, eosinophils, basophils, mast cells, and dendritic cells. Anatomically they are abundantly found in the locations where they encounter most pathogens, such as submucosal tissue of the respiratory system, gut, skin, and urogenital tract (Rabinovitch, 1995).

The initiation of phagocytosis is dependent on the interaction of microbial surface with certain receptors on the phagocytes. Subsequently, the bounded microorganism is surrounded by the cell membrane of the phagocytes and internalized in a vesicle named “phagosome.” Then, lysosomes which are enriched in antimicrobial enzymes are fused into phagosome leading to the formation of “phagolysosome.” In this context, pathogen killing would occur through the enzymatic process or by the influence of antimicrobial peptides present in phagolysosomes (Fig. 1) (Flannagan et al., 2012).

Several receptors have been identified that stimulate the phagocytosis and intracellular killing of pathogens. “Dectin-1” is expressed by macrophages, neutrophils, and dendritic cells which recognizes the polymers of glucose especially on the fungal cell wall (Herre et al., 2004; Dambuza and Brown, 2015). Furthermore, “Mannose receptor” (MR) is expressed by macrophages and dendritic cells which recognizes mannose residues in bacteria, virus, and fungi (Ezekowitz et al., 1990). Also, “Scavenger receptor” (SR) on macrophages identifies different anionic polymers and low-density lipoproteins (LDL) (Peiser et al., 2000).

Phagocytosis could be enhanced by binding of some components named “opsonins” to the pathogen. Immunoglobulins and complement fragments (e.g., iC3b) are identified as the key opsonin molecules which induce efficient phagocytosis (Rosales and

Fig. 1 The effector mechanisms of innate immune system. *Ig*, Immunoglobulin; *ADCC*, antibody-dependent cell cytotoxicity; *NK*, natural killer cell; *Eos*, eosinophil; *MQ*, macrophage; *COM*, complement.

Uribe-Querol, 2017). Therefore, complement receptors (CRs) and Fc receptors (FCRs) are the other receptors that facilitate phagocytosis and enhance pathogen killing function (Fig. 1) (Rosales, 2007).

During the pathogen killing by phagocytosis, some toxic compounds are produced that including superoxide (O_2^-), hydroxyl radical, nitric oxide (NO), hypochlorite (HOCl), and hydrogen peroxide. This process is accompanied by a mechanism known as the “respiratory burst” which included a transient increase in oxygen consumption by the phagocytes. There is another mechanism to pathogen take up known as “macro-pinocytosis.” In this way, large amounts of extracellular fluid along with the microorganism are ingested (Uribe-Querol and Rosales, 2017).

Inflammatory response: A process induced by pathogen recognition and tissue damage

Recognition of pathogens or damage-related molecules elicits an inflammatory response within initial hours of infection that results in increased infiltration of leukocytes to the affected tissue as well as elevated production of acute phase proteins (APPs). This response is accompanied by heat, redness, pain, and swelling at the site of infection (Kotas and Medzhitov, 2015; Nathan, 2002). Interestingly, inflammatory signaling induces blood clotting in small vessels at the site of infection which plays an important role in preventing the dissemination of infection throughout the body (Levi et al., 2003).

During inflammatory response, immune cells produce a variety of inflammatory mediators including the proteins or glycoproteins named “cytokines” and “chemokines.” Interleukin-1 (IL-1), IL-6, and tumor necrosis factor- α (TNF- α) are the most important pro-inflammatory cytokines produced by innate immune cells. These mediators increase the vascular permeability and the recruitment of the other innate or adaptive immune cells leading to the promotion of immune response against pathogen or injury (Gilroy et al., 2004; Headland and Norling, 2015). In this context, inflammatory response induces the expression of cell-adhesion molecules on the endothelial cells leading to the promotion of leukocytes binding and their migration from blood stream to affected tissue, a mechanism known as “extravasation.” Meanwhile, Neutrophils are the first leukocytes attracted to the infection site (Mitroulis et al., 2015).

Surface molecules of microorganisms also activate complement system leading to production of complement-associated molecules such as C5a or C3a which act as “anaphylatoxins” and increase the recruitment of immune cells to the infection site (Merle et al., 2015).

Complement system

Complement system as a pivotal effector mechanism of innate immune system is capable of destruction of a variety of microorganisms including bacteria, viruses, and parasites. This system consists of more than 30 soluble and cell surface proteins (Fig. 1) (Merle et al., 2015). Upon stimulation, these proteins being activated and initiate a cascade which results in:

1. Pathogen destruction by forming pores on the cell membrane of microorganism
2. Increased recruitment of inflammatory immune cells by production of “anaphylatoxins”
3. Enhanced phagocytosis by production of opsonins

The complement system could be activated by three pathways including:

1. Classical pathway: activated by the immune complexes of antigen-antibody
2. Alternating pathway: activated by the spontaneous hydrolysis of C3 component
3. Lectin pathway: activated by the recognition of certain carbohydrates on the microbial surface

An immune complex which consists of antibodies (IgG1 or IgM) attached to the cell surface of pathogens is capable of activating the classical pathway. In this manner, C1 complex (C1q, C1r, C1s) binds to the Fc region of antibodies. Upon activation, C1s acts as a serine protease and cleaves C4 and C2 into C4a, C4b and C2a, C2b, respectively. Subsequently, C4b along with C2a form C4bC2a complex which interacts with pathogen surface. This complex (C4bC2a) acts as an enzyme named "C3 convertase" which cleaves C3 into C3a and C3b fragments. This step is the point in which all complement pathways converge. C3b fragment covalently binds to the microbial surface and its association with C4bC2a makes a complex (C4bC2AC3b) named C5 convertase which in turn converts C5 into C5a and C5b. Binding of C5b to the microbial surface leading to activation of other components including C6, C7, C8, and C9. Ultimately, polymerization of C9 on the pathogen surface results in the formation of several pores named "membrane attack complex" or MAC which can directly lyse targeted pathogen. The lectin pathway is similar to classical pathway, but its activation is antibody-independent. In this pathway, pattern recognition receptors (PRRs), such as mannose-binding lectin (MBL) and ficolins recognize the carbohydrates on the microbial surface. MBL is complexed with MBL-associated serine proteases (MASPs)-1, -2, and -3 which their activation results in cleavage of C2 and C4, and subsequently the generation of the C3 convertase (C4bC2) of both classical and lectin pathways. The alternative pathway is activated with the spontaneous hydrolysis of C3 into C3a and C3b. In the presence of microbial infection, C3b binds to the microbial surface. Subsequently, the association of B and D factors with C3b leads to additional C3 cleavage and formation of alternative pathway C3 convertase (C3bBb) and C5 convertase (C3bBbC3b). A protein named "properdin" stabilizes alternative pathway convertases and facilitates alternative activation. Anaphylatoxins including C4a/C3a/C5a are potent inflammatory molecules which possess several functions such as increases in vascular permeability, leukocyte infiltration, smooth muscle contraction, phagocytosis and production of inflammatory mediators such as pro-inflammatory cytokines (Merle et al., 2015).

Antibody-dependent cell cytotoxicity (ADCC): An extracellular killing mechanism

ADCC could be considered as an extracellular killing mechanism resulting in pathogen elimination. This process requires: (1) immune cells expressing Fc receptor on their surface, and (2) target antigen coated by antibody (Fig. 1). Immunoglobulin G (IgG) and its receptor named FcγRIII (CD16) play an important role in ADCC activation. NK cells which express high levels of CD16 are regarded as the key players in this process. However, in addition to NK cells, macrophages, neutrophils, and eosinophils are able to mediating ADCC (Hubert et al., 2011; Siders et al., 2010; Valerius et al., 1990).

IgG possess a bifunctional structure which is related to the fragment antigen-binding (Fab) and Fc portions of antibody. ADCC is initiated by the engagement of Fab and Fc regions of antibodies with the pathogen and FcγR on effector cells, respectively. Subsequently, degranulation of effector cells (mainly NK cell) leading to pathogen lysis (Nigro et al., 2019).

The components of innate immune system

Physical and chemical barriers

The innate immune system includes anatomical and chemical barriers that impede microbes from entering the body. Epithelial cells which comprise the skin and the lining of the respiratory, gastrointestinal, and genitourinary tracts act as the first line of defense against pathogens. In addition to forming the tight junctions, epithelial cells produce a large amount of "mucus" enriched glycoproteins known as "mucins" which traps microorganisms and prevent their dissemination (Fig. 1). Epithelial cells also provide a chemical barrier by producing various chemical substances with antimicrobial properties. Digestive enzymes and acidic pH of the stomach, lysozyme, phospholipase A2, defensins, cathelicidins, and histatins are identified as the important chemical barriers to infection (Schleimer et al., 2007).

"Lysozyme" is a glycosidase enzyme in tears and saliva which has the ability to disruption of peptidoglycan present in the bacterial cell wall especially in Gram-positive bacteria. Paneth cells, a type of epithelial cells in the small intestine produce several microbiocidal proteins such as lysozyme and phospholipase A2 responsible to killing the pathogens in the gut lumen (Sukhithasri et al., 2013).

"Defensins" as the cationic peptides form a pore in the cell membrane of pathogens like bacteria and fungi as well as the viruses' envelope. Two distinct types of defensins with different activities and structure are implicated in humans including α - and β -defensins. Neutrophils and paneth cells produce α -defensins. The production of β -defensins is induced by infection considerably in skin, airway and urogenital tracts (Ganz and Lehrer, 1997; Ouellette and Selsted, 1996).

"Cathelicidins" are antimicrobial peptides produced by macrophages, neutrophils, mast cells, NK, T, B, sebocytes, and epithelial cells in response to infection (Roby and Di Nardo, 2013).

"Histatins" as the important anti-fungal peptides have a key role in host defense in the oral cavity. Histatins are primarily produced in response to pathogenic fungi such as *Cryptococcus neoformans* and *Candida albicans* (Edgerton and Koshlukova, 2000).

Innate immune cells

The most cells of the innate immune system are derived from myeloid lineage including neutrophils, eosinophils, basophils, mast cells, monocytes, macrophages, and dendritic cells. While others, including NK cells, natural killer T (NKT) cells, and innate lymphoid cells (ILCs) are originated from lymphoid lineage. These cells with distinct phenotypes contribute to pathogen killing through especial functions. Table 1 lists the innate immune cells and their effector mechanisms in host defense.

Monocyte and macrophage

Monocytes and macrophages are the important components of innate immune system which possess various inflammatory and regulatory capabilities. These cells are known as professional phagocytes and play the key roles including cytokine production, antibody-dependent cell cytotoxicity (ADCC), antigen presentation, T cell proliferation and activation, tissue repair and regeneration, resulting in pathogen elimination and tissue homeostasis.

Monocytes are developed in bone marrow and then circulate in the blood stream. These cells emigrate to different tissues throughout the body where they differentiate to macrophages and myeloid-derived dendritic cells. Three subpopulations of monocytes with distinct phenotypes have been found in humans which exhibit different functions. These are including classical (CD14⁺⁺CD16⁻), intermediate (CD14⁺⁺CD16⁺), and non-classical (CD14⁺CD16⁺⁺) monocytes (Ziegler-Heitbrock et al., 2010). Classical type comprises the largest population of monocytes that are highly skilled in phagocytosis and antibody-dependent cell cytotoxicity (ADCC). These cells are important in initiating the inflammatory responses. Non-classical types are known as anti-inflammatory monocytes that are involved in maintaining vascular homeostasis. Intermediate monocytes have several

Table 1 The major components and important functions of innate and adaptive immune systems.

Immune system	Components		Functions
Innate immunity	Physical and chemical barriers		Such as skin, mucus membrane, chemical secretions Prevent pathogens from entering the body, pathogen killing via cytotoxic mediators
	Monocytes and macrophages		Phagocytosis, act as professional APC, ADCC, T cell proliferation and activation, tissue repair and regeneration
	Dendritic cells		Initiating and polarization of the immune responses phagocytosis or macropinocytosis act as professional APC, ADCC, T cell proliferation and activation
	Neutrophils		Most numerous innate immune cells, phagocytosis, ADCC, promotion of both innate and adaptive immune responses formation of NETs
	Eosinophils, Basophils, Mast cells		defense against parasitic infections and allergic reactions, ADCC
	Innate lymphoid cells		promotion the adaptive immune responses, responding to pathogenic tissue damage, tissue homeostasis, repair and regeneration
	Natural killer cells		strong cytotoxic function importantly against virus-infected cells and cancerous cells, ADCC
Adaptive immunity	Natural killer T cells		recognize the lipid derivatives of pathogens presented by CD1 molecule, activation of other cells in innate and adaptive immune system
	B cells	B1 cells	Production of natural antibodies without the presence of any infections
		Follicular B cells	Most frequent B cells in the circulation, production of the majority of antibodies during an infection
		Marginal zone B cells	Defense against blood-born pathogens
	T cells	CD4 ⁺ T helper	Th1: Defense against intracellular pathogens, cytokine production, enhance phagocytosis, inducing B cells to make IgG1 and IgG3 antibodies
			Th2: Defense against extracellular pathogens, cytokine production, inducing B cells to make IgG4 and IgE antibodies
	Antibodies	CD8 ⁺ T cytotoxic	Defense against intracellular pathogens and cancerous cells, enhance phagocytosis
		IgG	The major antibody involved in opsonization and neutralization IgG have four subclasses: IgG1, IgG2, IgG3, IgG4
		IgA	High levels in mucosal tissues, saliva, tear, breast milk Have neutralization activity and moderate opsonization capacity, complement activation
		IgM	The first produced antibody upon infection Acts as membrane bound receptor for B cell Excellent complement activation
		IgD	No opsonization, moderate neutralization Membrane bound receptor for B cell
		IgE	No opsonization and neutralization activities The major antibody involved in parasitic infections and inflammatory conditions including allergy and asthma No opsonization, moderate neutralization

APC, Antigen presenting cell; ADCC, antibody-dependent cell cytotoxicity; TH, T helper; Ig, immunoglobulin; NETs, neutrophil extracellular traps.

functions including the production of reactive oxygen species (ROS), T cell activation by cytokine production and antigen presentation (Sampath et al., 2018).

Macrophages are found approximately in all tissues in the body. These cells are capable to recognition of the pathogens or damaged cells by several surface receptors such as SR, TLR, and NLR (Taylor et al., 2005).

Macrophages could be classified in to two important subtypes, including “M1 or classically activated macrophages” and “M2 or alternatively activated macrophages” that are different in their surface markers, produced cytokines, and functions (Yao et al., 2019).

M1 macrophages exert pro-inflammatory, anti-microbial and anti-tumoral activities, while M2 macrophages exhibit anti-inflammatory and immunomodulatory properties, tissue-repairing, pro-tumoral and pro-angiogenic functions, and possess effective phagocytic activity.

Macrophage polarization is highly dependent on the signals in the microenvironment. For example, LPS and cytokines of Th1 such as interferon gamma (IFN- γ) and TNF- α are identified as the main stimulator of M1 polarization. On the other hand, M2 macrophages are thought to be associated with Th2 cytokines such as IL-4, IL-13, IL-10, IL-33, and TGF- β (Yao et al., 2019).

M1 macrophages are produced in response to intracellular bacteria like *Mycobacterium tuberculosis*, *Listeria monocytogenes*, *Salmonella typhi*, *Salmonella typhimurium* (Benoit et al., 2008). These cells are characterized by the expression of CD80 (B7.1), CD86 (B7.2), MHC II, TLR2, and TLR4. During inflammatory responses, M1 macrophages produce pro-inflammatory cytokines and chemokines such as IL-1, IL-6, TNF- α , IL-12, CCL15, CCL20, CXCL9, and CXCL10 upon ligand recognition and promote the Th1-related responses (Yao et al., 2019).

M2 macrophages are mostly related to chronic infectious diseases like chronic brucellosis, chronic mycobacterial infections (Benoit et al., 2008). M2 macrophages secrete anti-inflammatory cytokines such as IL-10, TGF- β and they can stimulate Th2 responses. These cells express the markers including mannose receptor (CD206), CD163, CD209 (DC-SIGN) (Yao et al., 2019).

Dendritic cell

Dendritic cells are tissue-resident or circulating leukocytes which known as the important cells in making a linkage between innate and adaptive immune responses. These cells are important in initiating and polarization of the immune responses. Several functions of DCs are including:

1. Pathogen uptake through phagocytosis or pinocytosis
2. Antigen processing and its presentation to T cells resulting in triggering the adaptive immune responses; these cells are known as the professional antigen presenting cells (APCs)
3. Cytokine production

Functionally, DCs are divided into two types including immature and mature DCs (Hawiger et al., 2001; Steinman et al., 2003). Immature DCs are skilled in antigen (Worbs et al., 2017) phagocytosis or pinocytosis, while mature DCs have the ability to activate T cell responses. DC maturation is initiated by the recognition of pathogens or damage-associated molecules by mediating several receptors such as TLRs (Hemmi and Akira, 2005; Cerboni et al., 2013). Subsequently, they migrate from peripheral tissues to secondary lymphoid organs (e.g., lymph node) where they can activate T cell responses by acting as an APC. Mature DC express high levels of MHCII, CCR7, and co-stimulatory molecules which are essential for T cell activation. Besides, increased levels of pro-inflammatory cytokines have shown to be produced by mature DCs compared with immature DCs. The interaction between DCs and T lymphocytes leading to differentiation of T cells to different subtypes including Th1, Th2, Th17, or regulatory T cells (Treg) which can be influenced by cytokine profile in the tissue microenvironment or the type of recognized pathogen. For example, high levels of IL-12 and IL-4 in microenvironment have shown to be associated with Th1 and Th2 differentiation, respectively (Patente et al., 2019).

Heterogeneous population and different subtypes of DCs have been identified with different origin, phenotypes, and biological functions. Two main subtypes of DCs are including conventional (cDCs) and plasmacytoid dendritic cells (pDCs). cDCs (CD11c⁺ CD123⁻) are regarded as having high ability for antigen uptaking and presentation to naïve CD4⁺ T cells and shown to produce pro-inflammatory cytokines (Haniffa et al., 2013). pDCs (CD11c⁻ CD123⁺) are well-known for the production of type I interferon (IFN-I) during viral infection, although they also have other activities such as stimulation of T cells and NK cells and the production of pro-inflammatory cytokines (Swiecki and Colonna, 2015). In contrast to conventional DCs, these cells are abundantly found in blood stream.

In addition, monocytes could be differentiated to dendritic cells known as monocytes-derived DCs, during infection and inflammation (Schlitzer et al., 2015).

Neutrophil

Neutrophils are regarded as the most numerous innate immune cells which act as the first line of defense against infection. In response to pathogens, neutrophils rapidly migrate from the blood stream to the damaged tissue. CXCL8 as a chemotactic factor plays the important role in their recruitment. These cells play the important role in initiation of the inflammatory response importantly by phagocytosis and release the cytotoxic granules (Rosales et al., 2016). Some pathogens such as *Staphylococcus aureus* is shown to evade phagocytosis and therefore have the potential to suppress defense by neutrophils (Kumar and Sharma, 2010).

Neutrophils display the important functions resulting in the promotion of both innate and adaptive immune responses. Elimination the extracellular pathogens by phagocytosis is the most important function of neutrophils (Rosales et al., 2017). Upon stimulation with various stimuli such as microbial components or increased level of intracellular Ca²⁺, neutrophils release

their granules by a process known as “exocytosis” resulting in pathogen killing. Their granules enriched with various antimicrobial molecules such as cationic peptides, proteases, lactoferrin, myeloperoxidase, gelatinase, cathepsin G, elastase, proteinase 3, and azurocidin (Kumar and Sharma, 2010).

Deficiency in neutrophil-associated granules leads to the increased susceptibility to Gram-positive or Gram-negative bacterial infections. For example, cathepsin G-deficient and elastase-deficient mice are more susceptible to the bacterial infections by *Staphylococcus aureus* and *Escherichia coli*, respectively (Kumar and Sharma, 2010).

In addition to phagocytosis, neutrophils can fight against pathogens by forming neutrophil extracellular traps (NETs). Formation of NETs is important to localizing the early infection. NETs are consisting of neutrophil nuclear material (e.g., chromatin), cytoplasmic and granular proteins. Extracellular release of these components leads to bacterial degradation. NETs play an important role in defense against infections including *Shigella flexneri*, *Mycobacterium tuberculosis*, *Streptococcus pyogenes*, *S. aureus*, *Candida albicans*, fungus, and parasites such as *Leishmania amazonensis* (Kumar and Sharma, 2010).

Eosinophil

Eosinophils are the important cells in defense against parasitic infections and allergic reactions such as asthma, as well as in tissue homeostasis including tissue repair and remodeling. Upon stimulation by several stimuli such as cytokines, complement system proteins, and immunoglobulins, eosinophils are infiltrated from the blood stream to the inflamed tissue (Kita, 1996). Th2 immune response and their cytokines such as IL-4, IL-5, and IL-13 have the significant role in eosinophil recruitment and activation (Sher et al., 1990; Horie et al., 1997).

The important effector functions of eosinophils are including cytokine production, releasing cytotoxic granules, antibody- and complement-mediated cytotoxicity, phagocytosis, and eosinophil extracellular DNA traps. Eosinophils produce several cytokines and lipid mediators in response to pathogens resulting in the vascular permeability, constriction of smooth muscle, and increased secretion of mucus. These are including IL-6, IL-2, IL-8, TNF- α , INF- γ , TGF- α/β , GM-CSF, platelet-activating factor (PAF), leukotriene C4 (LTC4), and matrix metalloproteinases (MMPs). Upon activation, eosinophils release their granules containing different tissue-destructive mediators which contribute to promote the inflammatory response and killing parasitic pathogens. These include eosinophil cationic protein (ECP), eosinophil peroxidase (EPO), major basic protein (MBP), and neurotoxin derived from eosinophils (EDN) (Shamri et al., 2011).

IgG1 and IgG3 immunoglobulins were found to be effective in promoting eosinophil-mediated killing. These antibodies by interacting with immunoglobulin receptor named Fc γ RII expressed on eosinophils, induce degranulation of eosinophils. This process is well-known as ADCC which regarded as a main extracellular killing mechanism (Kaneko et al., 1995).

In addition, eosinophils are shown to exhibit the antibacterial role by releasing the materials consist of mitochondrial DNA as well as cytotoxic granule-derived components which acts as traps in order to pathogen killing. LPS of Gram-negative bacteria considerably induce eosinophil-derived extracellular traps (Yousefi et al., 2008).

Basophil

Basophils are the major immune populations involved in allergy response and hypersensitivity reactions including asthma, anaphylaxis, and allergic rhinitis. Besides, they contribute to immunity against helminthes and bacterial respiratory infection (Chirumbolo et al., 2018). Basophil-mediated responses could also be evoked by several bacterial infections such as *S. aureus*, *non-hemolytic streptococci*, *Haemophilus influenzae*, *S. enteritidis* and *E. coli* (Abraham and Arock, 1998).

These cells are capable to activate adaptive immune responses importantly the stimulation of Th2 immune responses. Basophils produce IL-4 and IL-13 cytokines which promote Th2 responses resulting in hypersensitivity reactions. Upon activation by several stimuli such as immunoglobulin E (IgE) binding, basophils release their granules containing histamine, heparin, and serine proteases. In addition, they can synthesize and release other mediators including leukotrienes and prostaglandins (Chirumbolo et al., 2018).

Mast cell

Mast cells are primarily involved in pathophysiology of allergic reactions and their functional mechanisms are similar to basophils. In contrast to basophils which are found in circulatory system, mast cells are mostly located in the skin, mucosal membranes and around blood vessels. Mast cells possess central functions in response against bacterial infections and certain parasitic infections. They can directly (opsonin-dependent) or indirectly (opsonin-independent) bind to the bacteria or parasites. In the indirect recognition (or opsonin-dependent), mast cells recognize the opsonized pathogens with complement fragments (e.g., iC3b) or immunoglobulins. *Salmonella typhimurium* and the helminth, *Schistosoma mansoni* have been reported to recognize by mast cells via this mechanism. In direct interaction, mast cells possess a striking capacity to recognize and bind to pathogen through their receptors without mediating opsonins. For example, *E. coli* and *K. pneumonia* and *Leishmania* parasites have been recognized to interact directly with mast cells (Abraham and Arock, 1998).

Similar to basophils, mast cells are highly skilled for the synthesis and production of several active mediators including histamine, heparin, serine proteases, leukotrienes, prostaglandins, cytokines, and chemokines in response to certain microorganisms (Galli et al., 1991; Galli, 1993). They produce various cytokines including IL-1, IL-6, TNF, IL-4, IL-5, IL-13, and chemokines MCP-1, MIP-1, RANTES. These mediators play central roles in the promotion of inflammatory responses, pathogen killing, enhanced phagocytosis, and development of adaptive immune responses. Besides, granule exocytosis contribute in pathogenesis of several allergic disorders causing hypersensitivity symptoms (Abraham and Arock, 1998).

Innate lymphoid cells (ILCs)

ILCs are a family of innate immune cells which primarily considered as the innate counterparts of T cells. They are tissue resident cells and abundantly found in mucosal surfaces especially in intestine and lung, and contribute in mucosal immunity and tissue homeostasis. ILCs are involved in several functions including promotion the adaptive immune responses, responding to pathogenic tissue damage, tissue homeostasis, repair and regeneration (Mjösberg and Spits, 2016; Ebbo et al., 2017).

ILCs are divided into three main groups based on their phenotype, cytokine pattern, and their developmental pathways, including ILC1, ILC2, and ILC3 (Vivier et al., 2018). ILC1s are significantly contributed to the promotion of macrophages and DCs activities and Th1 responses. In this context, they produce IFN- γ in response to up-regulation of IL-15 and IL-12 during infection or tissue injury. IFN- γ enhances the elimination of intracellular bacteria as well as antigen presentation by macrophages and DCs (Fuchs et al., 2013).

ILC2s are involved in the immune response against parasites infection and repair the damage caused by parasitosis or viral infections. They secrete cytokines such as IL-4, IL-5, IL-9, IL-13, and amphiregulin in response to IL-25, IL-33, and TSLP which promote Th2 responses and innate defense against parasites (Panda and Colonna, 2019).

ILC3s play an important role in response to extracellular bacteria and fungi. They produce IL-22 and IL-17 in response to IL-23 and IL-1 β and induce Th17 responses and neutrophil recruitment. These cells by the production of IL-22 contribute in the up regulation of antimicrobial peptides and enhancement of barrier integrity especially in the intestine (Aujla et al., 2008; Sugimoto et al., 2008; Zheng et al., 2008).

Natural killer cell (NK)

NK cells are a subset of innate lymphocyte cells that characterize by the strong cytotoxic function importantly against virus-infected cells and cancerous cells. The dominant population of NK cells express CD16 and CD56 molecules (Lanier et al., 1986, 1989). In respect to the NK cell phenotypes, two major subsets of NK cells are identified in humans in according to the expression of CD16 and CD56 markers as follows (Stabile et al., 2017):

1. CD16^{High}CD56^{Low} NK cells possess high levels of perforin mediating cellular cytotoxicity leading to the enhancement of pathogen killing
2. CD16⁺/CD56^{High} NK cells are characterized by the low levels of perforin and they are highly skilled in cytokine production

NK cells have multiple activating (e.g., KIR2DL, KIR3DL, NKG2A, CD85, and CD244) and inhibitory receptors (e.g., NKG2C, NKG2D, KIR2DS, KIR3DS, NKP30, NKP44, and NKP46) allow them to recognize the target cells. Upon activation, NK cells produce several cytokines and chemokines including IFN- γ , TNF- α , granulocyte macrophage colony-stimulating factor (GM-CSF), CCL1-CCL5, and CXCL8 leading to regulation of the function of other innate and adaptive immune cells (Paul and Lal, 2017).

MHC class I molecule which express normally on healthy cells is considered as a ligand for NK-inhibitory receptor and their interaction results in NK cell tolerance and inactivation. On the other hand, decreased level of MHCI is expressed on the virus-infected cells or tumor cells leading to engagement of the activating receptors and propagates cytotoxic activity of NK cells (Lanier, 2008).

NK cell cytotoxic response is dependent on forming an immunological synapse between NK cell and target cell. Upon activation, NK cells release their cytotoxic granules containing "perforin" and "granzyme." Released perforin by polymerization on the cell membrane of target cells forms the pores which facilitates the entry of granzymes into the target cells. Granzyme as a serine protease activates the enzymes known as "caspase" responsible to induction of cell death or "apoptosis" of target cells (Topham and Hewitt, 2009). NK cell-mediated apoptosis of target cells could also perform by engagement the receptors named "death receptor." These receptors such as TNF receptor and Fas receptor bind to cognate ligands on target cells and induce apoptosis of target cells (Sonar and Lal, 2015; Thorburn, 2004).

One of the important NK cell receptors, CD16 or Fc γ RIII, mediates an extracellular death named as antibody-dependent cell-mediated cytotoxicity (ADCC). This receptor by binding to Fc region of antibodies especially IgG, induces the degranulation of NK cells and promote killing the target cells (Mandelboim et al., 1999).

Natural killer T cell (NKT)

NKT cells are a subgroup of innate immune cells with cytotoxic functions which express NK cell markers and a type of T lymphocyte receptor named $\alpha\beta$ T cell receptor or $\alpha\beta$ TCR. These cells can early activate in response to IL-12 and IL-18 produced during microbial infections and is responsible to recognize the lipid derivatives of pathogens presented by CD1 molecule, a non-polymorphic MHC class I molecule on APCs. Upon activation, NKT cells secrete IFN γ and IL-12 resulting in the activation of other cells in innate and adaptive immune system including T cells, NK cells, and DCs (Terabe and Berzofsky, 2008). Gram negative-derived LPS is implied as the important stimulus for activating NKT cells. However, LPS-negative bacteria also have the ability to induce NKT responses (Van Kaer and Joyce, 2005). NKT cells are also contributed to response against parasitic infections like *Leishmania* and viral infections (Terabe and Berzofsky, 2008).

Adaptive immunity

Adaptive immunity, also known as acquired immunity or specific immunity is the second line of defensive response against invading pathogens. This type of immune response occurs to attack non-self pathogens however sometimes may mistakenly attack

self-tissues which results in autoimmune diseases such as lupus, rheumatoid arthritis, and etc. The difference between adaptive immunity and innate immunity is that the adaptive immune response is not immediately started as innate immune response occurs. However, the effect of the adaptive immune response is long-lasting and highly specific.

The adaptive immune system can learn and remembers specific pathogens, thus it can provide long-lasting defense and protection against recurrent infections. While the adaptive immune system is encountered to a new threat, some antigens are memorized to prevent from getting the disease again. One example of immunological memory is vaccinations. Both attenuated whole virus/bacteria and their particles cannot actually cause an active infection but cause an immune response. In other words, fail in the immunological memory system can result in autoimmune diseases. Molecular mimicry of a self antigen by an infectious foreign pathogen, including viruses and bacteria, can trigger autoimmune disease because of a cross-reactive immune response against the infection. *Streptococcus* infection is a good example in which a foreign organism uses molecular mimicry to hide from immunological responses (Chaplin, 2010). Furthermore, the activity of the adaptive immune system relies on the clonal expansion of T and B lymphocytes and also immune response mediators.

In overall, there are two types of the adaptive immune system (Fig. 2):

1. Cell-mediated immunity (or cellular immunity) that occurs against cells infected with viruses, intracellular bacteria, and cancerous cells, and mediated by helper and cytotoxic T lymphocytes.
2. The humoral immunity (or antibody-mediated immunity) is an efficient immunity against extracellular or circulating antigens. This type of immunity involves B cells differentiation into plasma B cells with aid of Type 2 helper T cells ($T_H 2$) that subsequently can produce immunoglobulins called antibodies.

In this section, we discuss in more detail about the components of adaptive immune system and their mechanisms of action in the specific immune response against pathogens.

Fig. 2 The effector mechanisms of adaptive immune system and the relation between innate immunity and adaptive immunity. BCR, B cell receptor; TCR, T cell receptor; Fab, fragment antigen-binding region; Fc, fragment crystallizable region; Fcγ R, Fc gamma receptor (receptor for IgG); MQ, macrophage; Neu, neutrophil; MO, monocyte; ADCC, antibody-dependent cell cytotoxicity; MHC, major histocompatibility complex; IFN-γ, interferon gamma; IL-2, interleukin-2; APC, antigen presenting cell.

Adaptive immune cells

The adaptive immune system depends on B and T cells responses. These cells are lymphocytes derived from specific types of bone marrow stem cells, known as multipotent hematopoietic stem cells. Upon formation in the bone marrow, these cells need to mature and activate. In this regard, each type of cell follows different developmental stages to become mature. T cells migrate to the thymus in where they complete their maturation into functional T cells. While, the development of an important part of B cells takes place in the fetal liver and bone marrow and then the immature B cells migrate to the spleen for their final stages of maturation (Huston, 1997).

B and T cells possess antigen-specific receptors which enable them to recognize specific foreign antigens. In this respect, both B cell receptor (BCR) and T cell receptor (TCR) use the process known as “gene rearrangement” to provide the necessary diversity of receptor specificities during developmental process of T and B cells in thymus and bone marrow, respectively (Gellert, 2002).

B lymphocytes

The mature B cells or naïve B cells have distinctive surface antigen-specific receptors (BCR) called membrane-bound antibodies. These surface antibodies are primarily IgM and IgD which can recognize epitopes associated with different types of antigenic structures including proteins, polysaccharides, and lipopolysaccharides. B cell receptors play important roles in antigen binding, internalization and processing of the antigen, and inducing signaling pathways such as the cytokine production pathway in order to communicate with other cells of the immune system.

B cell activation occurs upon antigen recognition in the secondary lymphoid organs such as lymph nodes or spleen. After binding an antigen to BCR, B cells quickly divide to either a memory B cell or an effector B cell (or plasma cell). Memory B cells express the membrane-bound antibody, while plasma B cells can secrete antibodies. Secreted antibodies identify and neutralize the free pathogens circulating throughout the body (Fig. 2) (Pieper et al., 2013).

Two sub-classes of B cells have been identified with distinct phenotype and function including B1 and B2 cells. B1 cells are found in the peripheral organs and they less commonly present in the blood. They are highly skilled in the production of natural antibodies without the presence of any infections. B2 cells are divided into two types including B follicular (BFO) and B marginal zone (BMZ). BFOs are the most frequent B cells in the circulation. They produce the majority of antibodies during an infection. BMZs are found primarily in the marginal zone of the spleen and they are involved in defense against blood-borne pathogens (Pieper et al., 2013).

T lymphocytes

Unlike antibodies, T cell receptors can't bind to antigens directly. They recognize the antigens bound to the membrane surface molecules on APCs, known as Major Histocompatibility Complex class 1 (MHC I) and class 2 (MHC II). During a recombination process in their genes, T cell receptors undergo a gene rearrangement that allows them for diverse binding. However, in order to an appropriate immune response and avoid mistakenly attack against self antigens, mature T cells should recognize only pathogens' antigens bound to the MHC molecules. Therefore, T cells undergo two “selection processes” during their developmental stages in the thymus; Positive selection in which T cells should bind self-MHC: peptide complexes and thus distinguish between self and nonself peptides and proteins. T cells that bind moderately to MHC complexes on the thymic cells receive survival signals. If these cells bind too strongly to these MHC complexes, they fail the positive selection and should be eliminated through apoptosis mechanism in the process of “negative selection.” Negative selection guarantees self-tolerance by testing the specifically binding ability of T cells to self-MHC: peptide complexes. The critical importance of these two selection processes is the protection of own cells and tissues against immune response, and otherwise autoimmune diseases would occur much more common (Chaplin, 2010).

Effector mechanisms of adaptive immune response

In an adaptive immune response, the effector mechanisms by which pathogens are eliminated are essentially similar to those of innate immunity. On the other hand, specific recognition by clonally distributed receptors during an adaptive immune response seems to be evolved as a late additional mechanism to existing innate mechanisms of action.

Antibodies: The effector mechanism of humoral immunity

Antibodies, as the products of plasma B cells in adaptive immune system, are found in the body fluids such as whole blood, serum or plasma, and also extracellular fluids. Thus, immune response mediated by antibodies is known as humoral immune response.

As shown in Fig. 2, an antibody molecule has Y-shaped structure whose identical arms function as two antigen-binding sites known as “antigen binding fragment” or Fab. However, these sites are highly variable from an antibody molecule to another which results in diverse specific antigen recognition. The stem of the Y structure which referred as “fragment crystallizable region” or Fc is a constant region which determines the class of the antibody and its functional properties. Five classes of antibodies including IgG, IgM, IgD, IgE, and IgA have been identified that each class uses diverse distinct set of effector mechanisms for recognition and elimination of antigens (Table 1). Through a mechanism known as “neutralization,” antibodies neutralize pathogens or their toxic products by binding to them and thus preventing them to enter cells and subsequent their infection. This mechanism is critical for protection against bacterial toxins and also pathogens such as viruses. Another mechanism by which antibodies can response to pathogens is known as “opsonization.” By opsonization, antibodies enable phagocytes for ingesting and destroying the extracellular

bacterium. The phagocytes recognize the **Fc region** of the antibodies coating the pathogen and foreign particles (Fig. 2). The third effector mechanism of antibodies is activation of several plasma proteins known as complement system. However, the complement system can also be activated without the function of antibodies in case of many microbial surfaces. Thus, this mechanism has important roles in both innate and adaptive immunity. In fact, the complement components by pore formation in surface of **bacteria** can directly destroy them, a critical function for some bacterial infections. Nonetheless, the main role of complement system is coating the surface of pathogens and enabling phagocytes to ingest and digest bacteria (Forthal, 2015).

Antigen presentation: A mechanism for T cells activation which is mediated by MHC molecules

T lymphocytes receptors are specialized to recognize a foreign antigenic peptide fragment bound to an MHC molecule. MHC molecules are membrane glycoproteins which composed of two types including MHC class I and MHC class II. These molecules are expressed considerably in APCs including dendritic cells, macrophages, and B cells. They trap and carry their cargo of peptide and transport to the cell surface, where the peptide is displayed to T cells (Fig. 2) (Blum et al., 2013).

In overall, antigen presentation process by APCs can be divided into four steps:

1. Antigen recognition and its uptake by APCs
2. Digestion of antigens
3. Loading the peptide epitopes on the MHC molecules
4. Antigen presentation in the form of MHC: peptide complex

The most important differences between the two classes of MHC molecule are the source of the peptides. MHC class I molecules trap peptides derived from proteins synthesized in the cytoplasm, and are thus able to display fragments of viral proteins on the cell surface that are recognized by cytotoxic T cells. MHC class II molecules trap peptides derived from proteins in intracellular vesicles, and thereby display peptides derived from pathogens living in macrophage vesicles or internalized by phagocytes and B cells which eventually are recognized by Th1 or Th2 cells (Blum et al., 2013).

In order to antigen-specific activation of these T cells and distinguish between the two classes of MHC molecule, two types of co-receptors are involved. CD8 co-receptor is expressed in cytotoxic cells and binds MHC class I molecules. Meanwhile, Th1 and Th2 cells express the CD4 co-receptor which binds MHC class II molecules.

Upon recognizing their targets, the effector T cells are stimulated to produce and release various mediators to affect their target cells or help to recruit other effector cells. Such effector mediators include many cytokines have a crucial role in the clonal expansion of lymphocytes and also in innate immune system and in the effector actions of most immune cells (Blum et al., 2013).

T cell response: The effector mechanism of cellular immunity

Compared to the B cells, T cells have a variety of effector actions. Some pathogens including viruses, parasites, and some bacteria for replication needs to enter cells where they don't be detected by antibodies. T cells, as responsible for the cell-mediated immune responses in adaptive immunity, eliminate these intracellular pathogens.

There are two major types of T cells including helper T cell (T_H) and cytotoxic T cell (CTL). As the name indicates, helper T cells help other immune cells to respond against pathogen. T_H cells express CD4 molecule on their cell surfaces and have role in defending the body against pathogens by activate the other immune cells especially through producing cytokine including $IFN\gamma$, IL-2, and TNF. They recognize peptide antigens presented with the form of MHC II: peptide complexes by APCs (Chaplin, 2010).

$CD4^+$ T cells are divided into two major subsets. The first subset of $CD4^+$ T cells are Th1 cells that is important in the inhibition of intracellular bacterial infections. The important examples of such **bacteria** which grow only in the macrophages are *Mycobacterium tuberculosis* and *Mycobacterium leprae*, the pathogens that related to tuberculosis and leprosy, respectively. Upon phagocytosis by macrophages, bacteria grow in intracellular membrane-bounded vesicles, and then destroyed in the lysosomes containing various enzymes and antimicrobial substances. These infections can be controlled by $CD4^+$ T cells that activate macrophages, and induce fusion of their lysosomes with the vesicles containing the bacteria and even also stimulate other mechanisms of the phagocyte in antibacterial action. In overall in order to pathogen clearance, Th1 cells play the important roles including:

1. Enhance macrophage activation and phagocytosis
2. Increase macrophage infiltration to the sites of infection
3. Promote the cytotoxic T cells and NK cells responses
4. Induce B cell responses to make opsonizing antibodies and complement-activating antibodies importantly IgG1 and IgG3

Compared to $CD4^+$ Th1 cells that destroy intracellular pathogens by activating macrophages, another subset of $CD4^+$ T cells called $CD4^+$ Th2 cells have a specialized role in destruction of extracellular bacteria, parasitic helminth infections through activating B cells. Besides, they are involved in inflammatory conditions such as asthma and allergy. They produce several cytokines including IL-4, IL-5, IL-9, and IL-13 which have an important role in controlling the extracellular helminth infections such as *Schistosoma mansoni* (Oliphant et al., 2011).

The important functions of Th2 cells in adaptive immunity are as follows:

1. Induce B cell responses to make antibodies IgG4 and IgE
2. Recruitment and activation of the inflammatory cells including basophils, mast cells, and eosinophils

Cytotoxic T cells are the essential subset of T cells involving in response against intracellular pathogens like viruses as well as cancerous cells. These cells express CD8 molecules on their cell surface and they can control the infection by directly killing the infected cells. They recognize peptide antigens presented with the form of MHC I: peptide complexes by APCs. Their killing mechanisms are depending on two types of cytotoxic proteins in their granules named as perforin and granzymes which allow them to attack and destroy infected cells. CD8⁺ CTLs produce IFN- γ which acts several functions including the inhibition of viral replication, increase MHC I expression, and macrophage activation (Chaplin, 2010).

Introduction

The immune system is composed of a number of organs and tissues that work together to promote immune cell development and maturation or to concentrate immune responses against an antigen. The anatomical organization of immune cells in lymphoid tissues and their ability to circulate and migrate between blood, lymph, and tissues play an important role in triggering immune responses. In fact, the immune system must be able to respond quickly to the small number of pathogens that enter the body from anywhere. Therefore, the presence of organs involved in the concentration of immune cells and antigens is essential for an effective immune response.

The physical barriers act as the first line of defense against infection through restricting the ingress of pathogens into the body. These include the skin, mucosal epithelium, and the respiratory cilia. Besides, several chemical barriers are also effective in neutralizing offensive microorganisms and infections, including:

1. The fatty acids present in the sebaceous glands
2. Antimicrobial defensins
3. Hydrolytic enzymes present in body secretions
4. The acidic pH of gastric

In addition, there are special organs that compensate for the probable failure of the first line of defense through generating humoral and cellular responses. In general, the lymphoid organs can be divided into “primary” (e.g., bone marrow and thymus) and “secondary” organs (e.g., spleen, lymph nodes, and mucosa-associated lymphoid tissue) based on anatomical location and immunological role (Fig. 1) (Picker and Siegelman, 1999).

Development of the mammalian immune system organs begins in an early embryonic stage and reaches its peak in early adulthood. However, certain components of the immune system begin to deteriorate around puberty.

Development of the primary organs of the immune system is a genetically determined process, usually completed early after birth, that leads to the organs with typical or normal microstructures. In contrast, the development of secondary lymphoid organs is

Fig. 1 The primary and secondary lymphoid organs and their locations in the human body. Created by [BioRender.com](https://www.biorender.com) (2021).

affected by environmental factors, in addition to the basic role of genetics. Furthermore, the primary immune organs also affect the development of the secondary lymphoid organs during the latter stages of life ([Parker, 2016](#)).

In this chapter, we will describe the primary and secondary lymphoid organs, their structures, and their role in the production and maturation of the various immune cells, as well as in immunity. Finally, the significance of the lymphoid organs in immune cell trafficking as well as in the fate of tissue transplantation is also discussed.

Primary lymphoid organs

The thymus and bone marrow are key primary lymphoid organs that produce, develop, and select naïve lymphocytes in a process known as lymphopoiesis. While the secondary organs are a place to respond to foreign antigens, the primary lymphoid organs are a place for lymphocyte training, the emergence of specific lymphocyte receptors, and the deletion of autoreactive lymphocytes.

Bone marrow (BM)

The BM is a primary organ where the blood cells are produced through the hematopoiesis process. During this process, all blood cell types originate from a hematopoietic stem cell (HSC). These cells can differentiate into all blood cells, including RBC, platelets (megakaryocytic), myeloid, and lymphoid progenitors. Furthermore, myeloid cells (such as monocytes, dendritic cells (DCs), neutrophils, basophils, and eosinophils), B lymphocytes, as well as natural killer (NK) cells, all develop in the BM. Meanwhile, T cell precursors migrate to the thymus for further maturation. Besides, nonhematopoietic tissues, including chondrocytes, adipocytes, myoblasts, and osteocytes, originate from mesenchymal stem cells (MSCs) in the BM. The BM-derived MSCs have shown immunosuppressive features and prolonged survival properties, especially in transplantation studies.

Interestingly, in order to tolerance induction in organ transplantation, scientists try to simultaneously infuse BM-derived HSCs along with solid organ transplantation from the same donor. However, successful findings achieved from this strategy have been restricted to only studies on small experimental animals ([Andreola et al., 2011](#)).

Well-established evidence suggests that HSCs originated from the yolk sac, migrated to the liver during pregnancy, and eventually implanted in the bone marrow (BM). It seems that the aorta-gonad-mesonephros (AGM), an area in the fetus, acts as an intermediate site of the primitive hematopoietic cells. Indeed, the initial hematopoietic precursor cells in the fetus are developed from hematopoietic stem cells (HSCs) in AGM through a commitment process. These primary progenitor hematopoietic cells then migrate to the liver and spleen through blood vessels, where they transform into the main hematopoietic lineage, to seed the primary (bone marrow and thymus) and secondary (lymph nodes, spleen and MALT) lymphoid organs ([Kyriazis and Esterly, 1971](#)).

In general, there are two types of BM:

1. The red marrow with hematopoiesis activity.
2. The yellow marrow, which contains mostly fat cells, where hematopoietic activity does not take place.

Initially, the marrow of a newborn is thoroughly red, but then gradually replaced by yellow marrow through time. Upon puberty, only flat bones have red marrow, including the sternum, cranium, vertebrae, scapulae, and pelvis, as well as the epiphyseal heads of long bones such as the humerus and femur (Moore and Metcalf, 1970; Parker, 2016).

The red tissue of the BM includes hematopoietic islands and fat cells, as well as vascular sinusoids distributed all over the trabecular bone. These hematopoietic islands provide a microenvironment comprising blood cell progenitors with different levels of maturation, endothelial cells, stromal reticular cells, osteoblasts, osteoclasts, macrophages, and the extracellular matrix. In addition to organizing blood cell maturation, this microenvironment also produces growth factors, chemokines, and cytokines. Upon maturation, blood cells enter the blood stream by migration through spaces between the basement membrane and endothelial cells of the vascular sinusoids (Romaniuk et al., 2016; Travlos, 2006).

Bone marrow as a place for the development of B lymphocytes

There are a variety of cells in the BM microenvironment that promote the development and growth of B cell precursors by providing important growth factors, adhesion molecules, chemokines, and cytokines (e.g., IL-7, thrombopoietin, Flt3 ligand, and CXCL12). B cell precursors are closely related to stromal reticular cells, the inner wall of the bone (endosteum), and the central sinus. The reticular cells next to the endosteum are the first cells involved in the evolution and growth of B cell precursors. There are other cells in the BM called adventitial reticular cells, which facilitate the entry of mature B cells into the bone marrow sinusoids and eventually the central venous sinus. Finally, mature B lymphocytes enter the bloodstream through the central venous sinus. Immature B cells released from the BM migrate to the spleen to become mature B cells.

During B cell lymphopoiesis, the production of specific B cell receptors (BCR) occurs in a process called “receptor rearrangement.” In this process, B cells undergo rearrangement in their immunoglobulin genes to express cell-surface immunoglobulins. In the process of lymphopoiesis in the BM, the developmental stages of B lymphocytes include ProB, PreB, immature B, and mature B, respectively. The ProB cell is the first cell that initiates gene rearrangement, and the heavy chain of IgM is the first chain to be rearranged. This cell contains the enzymes needed for rearrangement, including Recombination-Activating Gene-1 (RAG1), RAG2, and Terminal deoxynucleotidyl Transferase (TdT). Eventually, the ProB turns into a PreB. The PreB begins to rearrange the light chain, and this cell is the first cell to have a receptor called pre B cell receptor (preBCR). The preBCR consists of three chains, including CD79, μ chain, and the surrogate light chain (SLC). PreBCR signal transmission is an important factor in the differentiation of PreB into immature B cells. Immature B cells, after the selection process and, if necessary, undergoing the phenomenon named “receptor editing”, eventually become mature B cells.

As mentioned, immature B cells in the BM are selected in order to delete cells that are potentially autoreactive. At this point, if the B cell receptor expressed on immature B cells binds to insoluble surface antigens of BM stromal cells, the B cell must be deleted or its receptor modified during the receptor editing process to no longer bind to self-antigens. However, if receptor editing also fails, immature B cells that express high-affinity receptors for self-antigens are deleted through apoptosis. On the other hand, a number of B cells that have no interaction with self-antigens will go through the evolutionary process of maturity (Fig. 2) (Kincade, 1981; van de Pavert and Mebius, 2010).

Cell transportation across the BM

Cell transportation/migration to and from the BM is principally modulated by several adhesion molecules, chemokines, and receptors. For instance, the integrin VLA4 (integrin $\alpha 4 \beta 1$) helps maturation of the B cells through its binding to the stromal cells via the ligand VCAM1. Also, the chemokine CXCL12, produced by stromal reticular cells and osteoblasts, maintains HSCs and myeloid and lymphoid cells in the BM through binding to its receptor CXCR4. In this way, some people with WHIM syndrome, who carry the “gain of function” mutations in CXCR4, show increased retention of leukocytes in the BM (pan-leukopenia).

CXCR4 antagonists, such as plerixafor, on the other hand, prevent the transport of HSCs, myeloid and lymphoid cells from the BM into the bloodstream. Animal studies also showed that the receptor CCR2 and its ligand CCL2 play a critical role in monocyte trafficking in the BM of the mouse (Hooper and Macpherson, 2010).

Thymus

The thymus is another primary lymphoid organ placed above the heart in the upper chest of mammals. In most species, the thymus originates from the pharyngeal pouches III and IV and is then located in the anterior mediastinal area. The matrix of most lymphoid organs is developed from fetal mesenchymal cells, but the thymus stroma develops mainly from epithelial cells (endoderm) and from mesenchyme (Anderson and Takahama, 2012).

This lymphoid organ has a central role in the development of the bone marrow-derived thymocytes into T lymphocytes. The thymus is one of the major organs of the mammalian adaptive immune system where CD4⁺ and CD8⁺ T cells are produced. Besides, in the thymus, T lymphocytes are trained in order to distinguish between self- and non-self-antigens. Maturation of the thymus is completed until prior to adolescence, and then its function gradually decreases.

Due to the important role of the thymus in the maturation of T cells, surgical removal of the thymus at birth results in severe immunodeficiency, while its removal after puberty has no significant outcome on the immune responses. One of the well-known examples of human diseases that establishes the vital role of the thymus in T cell development is DiGeorge syndrome. In this disease, the affected individuals are characterized by congenital loss or severe hypoplasia of the thymus, as well as few T cells but a normal population of B cells (Anderson and Jenkinson, 2001).

Fig. 2 Immature B cells are tested for autoreactivity before they leave the bone marrow. Created by [BioRender.com](https://www.biorender.com) (2021).

The human thymus matrix derives from three origins, including the endodermal pharyngeal pouch III, the ectodermal branchial cleft, and the stromal pharyngeal arch (i.e., the neural crest). It seems that the interaction between the epithelial cells of the endoderm and ectoderm is necessary for thymus development. Besides, the participation of the neural crest is required for the development of the thymus medulla. The formation of the fetal thymus depends on both the development of epithelial and lymphatic components. The sequence order of the primary lymphocyte origin comes from the hematopoietic sites of the yolk sac and/or AGM, fetal liver, and finally in the postnatal period from BM, respectively. Entrance of a population of naïve T cells into the thymus depends on the successful maturation of the offspring of progenitor cells. Indirect evidence shows that mature thymocyte populations accumulate in the thymic cortex (Anderson and Takahama, 2012).

The thymus plays a central role in tolerance, through the production of nTreg and the negative selection of newly developing T cells. Today, scientists try to use this potential of the thymus to induce tolerance in solid organ transplantation through the mixed hematopoietic chimerism approach (e.g., by co-transplantation of thymus and kidney grafted from the same donor to MHC-mismatched recipients). The basic principle behind this plan is based on the evidence that donor HSC-derived DCs prompt apoptosis in newly developing donor-reactive T cells in the thymus, which results in central tolerance. Furthermore, the epithelial cells of the thymic graft cause central tolerance through their ability to express donor antigens such as donor MHC antigens, and also eliminate donor-reactive T cells from the recipients (Yamada et al., 2020).

Thymus structure

Thymus has a lobular structure consisting of two distinct zones: cortex and medulla (Fig. 3). The cortex is the site of a concentrated population of immature T cells during their development, while the medulla is occupied by mature T cells. It seems that the T precursor cells ingress the thymus and proliferate in the cortex area.

Besides, a highly vascularized corticomedullary boundary separates these areas. Several types of cells are present in the cortex and medulla of the thymus, including epithelial cells, stromal cells, dendritic cells, and macrophages. These cells form a cellular network that facilitates the maturation of thymocytes. Various cell types present in this thymic network contribute to thymocyte development in different ways, including direct interaction (stromal cells); and acting as nurse cells with surrounding thymocytes (epithelial cells).

The constituent stroma of both the cortex and the medulla is a three-dimensional matrix of thymic epithelial cells (TECs) enclosed by T lymphocytes. Depending on whether TECs are placed in the cortex or medulla, they are called cortical TECs (cTECs) and medullary TECs (mTECs), respectively.

The cTECs facilitate positive selection by expression of MHC class I and II molecules that help in processing and presenting self-peptides. At this point, thymocytes that recognize self-peptides:MHC complex with moderate affinity are allowed to survive. Otherwise, they do not receive a survival signal and become apoptotic.

Fig. 3 Thymus as a primary lymphoid organ and its structure, consisting of the cortical and medullary regions. Created by [BioRender.com](https://www.biorender.com) (2021).

Positive selection is a phenomenon involving the restriction of T cells to MHC, which ensures that T cells recognize antigens only if they are presented to them in the form of an MHC:peptide complex.

The mTECs present many types of organ-specific peptides. These cells are the main cause of the negative selection of thymocytes. During negative selection, cells whose TCR detects thymic peptides:MHC complexes presented by mTECs, macrophages, or dendritic cells at the cortico-medullary junction or in the medulla with high-affinity undergo negative selection and apoptosis. But those with low or moderate affinity for thymic peptides:MHC complexes survive and exit the thymus (Itoh et al., 1999).

The medulla in the human thymus also has distinguishable parts called Hassall's corpuscles, containing the dense layers of keratinizing epithelium, where T cell apoptosis and production of thymic stromal lymphopoeitin (TSLP) occur. It seems that TSLP participates in the activation of thymic DCs (Bleul et al., 2006).

Thymus functions in the immune system

As mentioned previously, maturation and selection of T cells are necessary for their ability to identify foreign peptides based on the MHC-restricted antigen recognition, and the thymus has a principal role in this process. For beginning maturation in the thymus cortex, bone marrow-derived T cell progenitors can enter the thymus through the venules next to the corticomedullary barrier. In order to further maturation, T cells acquire classical markers such as CD4 and CD8, then undergo random rearrangement in their T cell receptors (TCR), which are requisite for positive and negative selection. Upon completion of T cell selection in the thymus medulla, they enter the blood stream (Miller, 1961).

Studies have shown that the DCs derived from bone marrow also significantly participate in T cell maturation and selection. Furthermore, a group of TECs located in the corticomedullary region contribute to the production of IL-7, which is vital for T cell survival. The mTECs in the thymus, through expression of a gene known as autoimmune regulator (AIRE), present peptides derived from proteins (such as insulin) to developing thymocytes in order to delete the autoreactive T cells specific to self-antigens. Mutations in the AIRE gene lead to an autoimmune disorder known as autoimmune polyglandular syndrome type I, also called autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) in humans (Yarilin and Belyakov, 2004).

In addition, the thymus plays several important functions, including generating NKT cells, $\gamma\delta$ T cells, and natural regulatory T cells (nTreg). NKT cells are positively selected (having both CD4 and CD8) in the thymus via the non-classical MHC molecule CD1d. These cells help to recognize the glycolipids generated by some pathogens, including mycobacteria. Besides, upon selection of the $\gamma\delta$ T cells in the thymus, they migrate to the gut and skin epithelium. The nTreg, as the CD4⁺ T cells, are also positively selected in the thymus and express the typical $\alpha\beta$ TCR and have a mediocre reaction with self-MHC and self-peptides. These cells regulate immune responses through suppressing the activity of effector T cells. Animal studies have shown that thymectomy upon birth or at the third post-natal day results in immunodeficiency and severe autoimmunity. The absence of nTreg is thought to be the root cause of such autoimmunity. In this way, mutation in Foxp3 (a transcription factor required for the development of Tregs) results in lethal autoimmune diseases, including immunodysregulation polyendocrinopathy, enteropathy X-linked syndrome (IPEX) in humans, as well as scurfy in mice (Takahama, 2006).

Cell transportation across the thymus

The trafficking of the cells in the thymus is critically dependent on the chemokines. Among the chemokines, CCL21 and CCL25 are examples that contribute to the trafficking of precursor cells from BM into the thymus through binding to the receptors CCR7 and CCR9, respectively. Furthermore, the chemokines CCL21 and CXCL12 have an important role in thymocyte maturation via binding to CXCR4 during the corticomedullary migration in the thymus. In addition, CXCL12 is essential for the migration of mature thymocytes from the thymus into the blood. Sphingosine-1-phosphate (S1P) is another mediator in the blood and lymph that aids in the emigration of mature thymocytes by binding to the S1PR1 receptor found on these thymocytes (Yan et al., 2017).

Secondary lymphoid organs

Secondary lymphoid organs are the sites of lymphocyte response to antigens and the production of effector and memory lymphocytes, in a process known as "immunopoiesis." The main secondary lymphoid organs are the spleen, lymph nodes, and mucosa-associated lymphoid tissue (MALT) consisting of cellular aggregates present in various submucosal membrane areas such as the intestinal lamina propria as well as the inner surfaces of the respiratory system, breast, thyroid, salivary glands, lungs, eyes, and skin.

Spleen

The spleen is a secondary lymphoid organ located under the pancreas and has an oval structure. The major function of the spleen is response to systemic infections (especially encapsulated bacteria) through filtering blood and capturing blood-borne antigens (Chadburn, 2000).

Development of the spleen during embryogenesis begins early in pregnancy. Like other secondary lymphoid organs, the complete development of the immune system compartments of the spleen depends on environmental factors. In the human fetus, the primordium of the spleen appears in the 5th week of pregnancy through proliferation of the mesoderm between the two lobes of the dorsal mesogastrium, and joins the stomach to the dorsal wall of the body. The dorsal mesogastrium fuses with the peritoneal wall, causing attachment of the spleen to the dorsal wall of the body through the lienorenal ligament, and to the stomach through the gastrosplenic (or gastrosplenic) ligament (Chadburn, 2000).

Spleen structure

The spleen is a highly vascularized organ. From the histological point of view, it is much more complicated than the thymus. The spleen is composed of two regions: the "red pulp" and the "white pulp" (Fig. 4). The red pulp contains large blood venous sinusoids with RBCs as well as platelets. On the other hand, the immunologic functions of the spleen are more related to the white pulp (Cesta, 2006).

The internal part of the spleen is separated by capsular connective tissue patterns known as trabeculae that further constitute regions called red pulp and white pulp that are spread throughout the spleen. The red pulp consists of a network of sinusoids rich in RBCs as well as macrophages, in which the old and deficient RBCs are eradicated and picked up. The white pulp encloses the arteries, and is enriched mostly with T lymphocytes, which form the periarterial lymphatic sheath (PALS). Furthermore, the marginal area near PALS is composed of the B cells produced in lymphoid follicles. The preliminary activation of B and T cells occurs in PALS, which is rich in T cells. This area is composed of interdigitating dendritic cells that entrap and present antigens via MHC class II to Th cells. This action results in T cell activation, which in turn induces B cell activation. The activated B and T cells subsequently move to the primary follicles in the marginal zone. Upon antigen induction, these primary follicles turn to secondary follicles. The secondary follicles are similar to the germinal parts of lymph nodes, where B cells proliferate (Cesta, 2006).

The role of the spleen in the immune system

The spleen has several functions, including hematopoiesis, storage, clearing of aged and damaged blood cells and platelets, as well as defense actions such as removing opsonized bacteria. Besides, this lymphoid organ has an important role in triggering adaptive immune responses. Thus, the absence of a spleen, as in splenectomy, makes humans and experimental animals extremely vulnerable to sepsis caused by encapsulated bacteria (e.g., *Streptococcus pneumonia*) and certain immunologic defects (Cesta, 2006).

The immune response is mainly concentrated in the "white pulp" composed of PALS and lymphoid follicles. Although PALS is usually considered as a site enriched in T cells, PALS has a major inner area filled with T cells and an outer area filled mainly with B cells, as well as fewer T cells and macrophages. Follicles usually develop at the junction of the T-cell and B-cell areas of PALS, similar to the follicle development in a lymph node. The marginal zone (MZ) surrounding PALS and follicles is occupied by populations of macrophages, and a specific population of B cells called marginal zone B cells (MZB). MZB is mainly found in the spleen and has

Fig. 4 The spleen and a tissue section of its structure. Created by BioRender.com (2021).

special functions, including high-level response to polysaccharide antigens (e.g., the antigens presented on the capsule of certain bacteria). Deficiency in this specific defense role (e.g., in a traumatic injury situation requiring surgical removal of the spleen) causes the host extremely vulnerable to bacterial infections with the pathogen having polysaccharide-rich capsules such as *Streptococcus pneumoniae*, which causes pneumonia in humans (Cesta, 2006).

Cell transportation across the spleen

The macrophages and immature DCs located in the MZ of splenic white pulp are responsible for removing pathogens such as microbes, antigens, as well as antigen–antibody complexes in the blood. The activation of T cells, as well as differentiation of B cells into memory B cells and antibody-producing plasma cells, are also facilitated in the T cell zones and border of the follicles of the spleen, respectively. Meanwhile, the maturation of the naïve B cells derived from the BM is completed in the spleen.

The existence of marginal zone macrophage and B cell populations are other unique properties of the spleen among the other secondary lymphoid organs. Due to the presence of macrophages, and the B cells expressing IgM and toll-like receptor 9 (TLR9), the spleen is considered as a defense system that mediates the presentation of the captured pathogens to the cells of the adaptive immune system. Furthermore, transmigration of the naïve T and B cells occurs in the white pulp of the spleen through the marginal sinus and then confined to the PALS and follicles stimulated by the chemokines CCL19/CCL21 and CXCL13, respectively. However, the related mechanisms are not well recognized (Lewis et al., 2019).

Lymph nodes

A lymph node has an encapsulated and bean-shaped structure distributed across the lymphatic system throughout the body. The lymphatic system transfers the extracellular fluid between the tissues and the blood via the lymphatic vessels. Due to the existence of antigens and APCs in the lymphatic fluid, lymph nodes act as the sites for antigen presentation to T and B cells. The specialized blood vessels called high endothelial venules (HEVs) localized to specific regions in the lymph nodes provide a place for the entrance of lymphocytes. Based on their function and the difference in the adhesion molecules expressed, lymph nodes are categorized into peripheral or mucosal types that are functionally distributed in the body (Arno, 1980).

The structure of lymph nodes

Lymph nodes are structurally encircled by a capsule along with medullary and subcapsular sinuses (Fig. 5). Lymph fluid infiltrates in lymph nodes via the afferent and efferent lymphatic vessels. A duct network composed of fibroblastic reticular cells, collagen, laminin, and fibrillin layers provides deep penetration of lymph containing antigens into the lymph node parenchyma in which the antigens are picked up by APCs or DCs that reside within lymph nodes. Then, the mature APCs carrying antigens migrate through lymphatic vessels and localize in T cell areas directed by chemokines (Arno, 1980).

HEVs are specialized post-capillary vessels that provide entry of T and B cells to lymph nodes. The cuboidal endothelial cells that cover these vessels express adhesion molecules and chemokines to facilitate T and B cell migration. B cells and follicular dendritic cells (FDCs) are orderly localized in follicles in the outer cortex, and T cells. On the other hand, they are diffused in the paracortical regions under the B cell follicles. In addition, these areas also include macrophages, stromal cells, and DCs. Furthermore, there are germinal centers consisting of the central parts of lymphoid follicles where antibody-producing plasma cells and memory B cells are produced. Finally, an internal area comprising medullary cords is also in the lymph node, which contains macrophages and plasma cells (Arno, 1980).

Fig. 5 The lymph nodes and their locations in the human body, along with a tissue section of their structure. Created by BioRender.com (2021).

Lymph node development begins during embryogenesis. For a long time, it has been generally believed that primitive lymph sacs grow from veins, and that lymph sacs act as the origin for the development of lymphatic as well as lymph nodes. Recent studies on mice have shown that primitive lymph nodes develop in the deficient mouse embryos, lacking lymphatic vasculature and lymphatic sacs, and also in the mutant embryos with defective lymph sacs. More recent studies showed that the structure of the lymph sac is not completely essential for the formation of lymph nodes, but they do not challenge the basic hypothesis that lymph nodes come from veins. Lymph node development needs the interaction of hematopoietic-derived lymphoid tissue inducer (LTi) cells with hematopoietic source and lymphoid tissue organizer (LTo) cells with mesenchymal source (Benezech et al., 2014).

Embryonic LTi cells can originate from fetal liver cells, which are the counterparts of common lymphoid progenitor cells in adult BM, while the LTo cells derive from adipocyte progenitors. LTo cells provide specific growth factors and signals that promote LTi cell migration and maturation, and also lymphocyte survival. Both embryonic and adult adipocyte precursor cells can differentiate into lymph node stromal cells, thus adipose tissue remains the source of adult lymph node stroma production. These interactions between adipose tissue and lymphatic structures may explain the appearance of lymphatic tissue in the omentum fat-associated lymphatic clusters, and finally, the association between adipose tissue and lymph nodes (Benezech et al., 2014).

The role of lymph nodes in the immune system

For their activation and maturation, naïve T and B cells initially need to be exposed to antigens in lymph nodes. Priming of naïve T and B cells takes place in the cortical zones (T cell zone), and in the follicles in the outer cortex of lymph nodes, respectively.

Lack of lymph nodes in mice leads to abnormalities in adaptive cellular and humoral immunity. Maintenance of naïve and memory T cells is another important role of lymph nodes that is facilitated via the presentation of self-antigens bound to MHC by the DCs that reside in the lymph nodes, thus providing survival signals to T cells. On the other hand, activated T cells via the membrane lectin CD69 on their surface are held in the lymph node to complete their proliferation and differentiation. However, many T follicular helper cells (Tfh) migrate into the B cell follicles and interact with B cells, which results in the generation of plasma blasts. Certain plasma blasts then migrate to the center of the follicle to divide and differentiate into memory B cells or antibody-producing plasma cells (Arno, 1980).

Cell transportation across lymph nodes

Like in other lymphoid organs, cell transition in lymph nodes is regulated by chemokines. For example, to migrate from non-lymphoid tissues into lymph nodes, DCs express the chemokine receptor CCR7 in response to CCL19 and CCL21 through a process called haptokinesis. Besides, naïve T cells and a group of memory T cells co-localize with DCs in the paracortical regions by expressing CCR7. Furthermore, naïve B cells migrate to follicles in the cortex, via interaction between their chemokine receptor CXCR5 and the chemokine CXCL13. In response to CCL21 expressed by mature DC, B cells express CXCR5 and receive help from activated CD4⁺ T cells. Moreover, T follicular helper cells also express CXCR5, and participate in B cell activation and germinal center formation. More recently, it has been reported that a group of regulatory T (Treg) cells called follicular Tregs inhibit B cell activation and humoral immunity (Cupedo and Mebius, 2005).

In general, T cells enter the lymph nodes initially through the binding of L-selectin (CD62L) located on the T cells to HEV. Depending on whether the lymph node is peripheral or mucosal, this binding is mediated by the peripheral node addressins (PNAd) (i.e., CD34 and GlyCAM-1), and MAdCAM-1 expressed on the endothelial cells, respectively. On the other hand, T cell adhesion and migration, are dependent on the binding of high affinity LFA1 (a 2 integrin) expressed on T cells to ICAM1 expressed on endothelial cells. Furthermore, the egress of effector T cells from the lymph node is mediated by sphingosine-1-phosphate (S1P) (Cupedo and Mebius, 2005).

Mucosa-associated lymphoid tissue (MALT)

Mucosa-associated lymphoid tissues (MALTs) comprise several nodules of partly encapsulated lymphoid tissue as well as feeble-associated lymphoid complexes located in epithelia and lamina propria of mucosal areas such as the gastrointestinal and respiratory tracts. These complexes are further categorized into gut-associated lymphoid tissue (GALT), bronchus-associated lymphoid tissue (BALT), and nasopharynx-associated lymphoid tissues (NALTs). Lymphoid tissues, including the appendix, tonsils, and Peyer patches, are characterized by their mucosal epithelium structure. By transporting foreign molecules through transcytosis to underlying lymphoid tissue in the gut and the respiratory system, the specialized microfold (M) cells of the follicle-associated epithelium of the MALT have a vital role in the production of immune responses. Furthermore, specific intraepithelial lymphocytes through strong cytolytic and immunoregulatory activities help mucosal tissue in defense against pathogens. Generally, MALT found in different tissues shows certain differences in function, structure, and development. However, all MALTs help to capture antigens through delivery of those antigens from the overlying epithelial surface and their presentation to the underneath cells of the immune system (Randall et al., 2008).

Gut-associated lymphoid tissue (GALT)

GALT is composed of separate or aggregated lymphoid follicles, which form Peyer's patch (PP). Peyer's patches (PP) are visible lymphatic structures that were first discovered in the human small intestine (Cornes, 1965). Due to the capability of PP to manage antigens and bacteria in the luminal areas, they are considered as the immunosensors in the intestine. The PPs comprise both follicle-associated epithelium and immune cells resident in the lymphoid follicles. Their interaction leads to immune defense

against pathogens as well as immunologic tolerance. These immune responses appear to be managed by pathogen recognition receptors, such as Nod2. In addition to the function of Toll-like receptors (TLRs) in PP homeostasis, Nod2 can also modulate the characteristics and population of T cells in PP, and in reply, these T cells can regulate cell permeability. Clinically, it has been reported that Crohn's disease and graft-versus-host disease (GVHD) in humans may be caused by NOD2 mutations, PP dysfunction, and subsequent immune malfunction during response to the normal flora (Randall et al., 2008).

Both the small and large intestines have GALT aggregates, but their GALT components are somewhat different. In other words, GALT is made up of PP, individual lymphoid follicles (ILF), cryptopatches (CP), and lymphocyte-filled villi in the small intestine, while diffuse lymphocytic populations are found in the mucosa of both the small and large intestines. Besides, lymphoglandular complexes are only in the large intestine. Postnatal development of some GALT components, including PP and diffuse lymphocytic populations, is different, and they may even show various immunobiological properties. However, both of them produce immunoglobulin A (IgA), vital for the function and maturity of the human gastrointestinal immune system, which is complete 2 years after birth (Randall et al., 2008).

Bronchus-associated lymphoid tissue (BALT)

BALT is a secondary lymphoid tissue that is only induced in humans during lung inflammation (known as iBALT); however, it is always present in rats and rabbits (Randall et al., 2008).

Nasopharynx-associated lymphoid tissues (NALTs)

The nasopharynx-associated lymphoid tissues (NALTs) are lymphoid aggregates in the posterior nasal cavity in rodents. These are thought to be equivalent to human tonsils and adenoids. In spite of the similarity in their function and structure, NALT and PP present considerable differences in their organogenesis and development. Furthermore, the HEV of NALT expresses the peripheral node address protein (PNAd), while the PP-associated HEV expresses MAdCAM1, and thus various initial B cell populations are found in NALT and PP (Csencsits et al., 1999).

Conclusion

As the primary lymphoid organs, the bone marrow and thymus are sites where the lymphocytes are produced, developed, and learn to distinguish self from non-self. The lymph nodes, spleen, and MALTs are the secondary lymphoid organs. The spleen is a blood filter organ supplying a context for interaction between innate and adaptive components, as well as their response to presented antigens. In other words, lymph nodes are a network connected by lymph vessels, that provide the drainage of antigens and interact with antigen-presenting cell populations to develop the engaged adaptive lymphocytes. MALTs are the diffuse cell aggregates connected to the epithelium and lamina propria of the mucus parenchyma, supplying foreign substances to the underlying lymphocytes.

Introduction

The “immune system” is made up of cells and molecules that protect the host body from harmful stimuli and keep the body in a state of homeostasis. The immune system’s components respond in a coordinated and comprehensive manner, resulting in the emergence of an “immune response.” While an optimal immune response would eliminate the harmful agent and restore homeostasis to damaged tissues, inappropriate responses can be harmful and result in tissue injury. As a result, immune system modulation is critical, allowing the organism to control the strength and duration of responses (Chaplin, 2010).

Any molecule that can be detected by the immune system is called an “antigen.” Parts of an antigen molecule that are recognized by immune system receptors are called “epitopes.” It is important to note that antigens that stimulate the immune responses are also called “immunogens.”

In summary, there are two types of immunity: “innate” and “adaptive” immune systems. The initial line of defense against infections is the innate immune system, which responds rapidly to stimuli. The innate immune response is known as “non-specific” immunity since it reacts to all foreign antigens in the same way. Adaptive immunity, on the other hand, is required for a successful immune response. The adaptive immune system identifies antigens more specifically than the innate immune system and can produce “memory” cells which have the ability to react quickly to pathogens in the second encounter (McCullough and Summerfield, 2005).

The immune system must detect and distinguish a wide range of antigens associated with infectious organisms or pathogens, including parasites, viruses, fungus, and bacteria, from the host’s own antigens in order to elicit an effective response. To this end, a number of receptors are present on immune cells which recognize pathogen-associated antigens (Medzhitov and Janeway Jr, 1998). The immune system must be tolerant to the host’s own molecules in order to avoid unwanted responses. This is a significant occurrence that establishes the theory of “immune tolerance.” Autoimmunity is a condition that occurs when self-tolerance is disrupted or when immune responses are improperly regulated (Chaplin, 2010).

In addition to responding to pathogens, the immune system is also responsible for protecting against other disorders, including cancer. On the other hand, defects or mutations in one or more parts of the immune system lead to the development of immunodeficiency diseases that can predispose a person to a variety of microbial diseases (Gonzalez et al., 2018).

In this chapter, we sought to present the fundamental principles of the immune system, covering the key components of lymphoid organs, immune system structure, innate and adaptive immunity, as well as the basic effective functions of the immune system to pathogen eradication.

Lymphoid organs

The immune system is composed of a variety of organs and tissues aimed at immune cell development and maturation, or concentrating immune responses against an antigen. The organs of the immune system include physical barriers such as skin and mucous membranes, as well as lymphoid organs. Based on the anatomical location and immunological role, the lymphoid organs can be divided into “primary” and “secondary” organs. The primary lymphoid organs include the thymus and bone marrow, which are the sites of lymphocyte production, development, and selection of naive lymphocytes, in a process known as “lymphopoiesis.” Secondary lymphoid organs, including lymph nodes, spleen, and mucosal associated lymphoid organs (MALTs), are the sites of lymphocyte response to antigens and the production of effector and memory lymphocytes, in a process known as “immunopoiesis” (Drayton et al., 2006).

Primary lymphoid organs

Thymus: a lymphoid organ for the development and maturation of T lymphocytes

The thymus is an organ located in the middle-anterior part of the thorax and in front of the aortic artery. This organ is made up of two lobes, each consisting of several lobules. The thymus is surrounded by a capsule of connective tissue, the branches of which extend into the thymus and divide it into different sections. The thymus is the most important center for regulating the function of the immune system and is created in the sixth week of the fetus. This organ is involved in the maturation and training of different types of T lymphocytes. The microenvironment in the thymus, such as the production of interleukin-7 (IL-7) and various hormones including thymosin and thymopoietin, plays an important role in the development of thymocytes. Epithelial cells in the central part of the thymus play a key role in the presentation of the host antigens to developing T cells, leading to the deletion of self-reactive T cells (a process known as self-tolerance or negative selection). Therefore, as mentioned before, the thymus is the most important center for the training and maturation of T lymphocytes. T-lymphocyte progenitor cells migrate to this organ from the fetal liver (during the embryonic period) and the bone marrow, and after development and proliferation, they become mature and functional T lymphocytes (Zdrojewicz et al., 2016).

Bone marrow: where the blood cells are produced through the hematopoiesis process

The bone marrow is the site of production of most blood cells, including red blood cells (RBCs), granulocytes, monocytes, and is the site of development and maturation of B-lymphocytes. The production of all blood cells is first done during the embryonic period in the hematopoietic islands of the yolk sac and mesenchyme around the aorta, then in the third and fourth months of pregnancy is transferred to the liver, and finally the bone marrow is the main site of hematopoiesis. Hematopoiesis occurs at birth in the bone marrow of the entire skeleton. In children, the marrow of the long bones such as the femur and tibia are the major sites of hematopoiesis. However, in adults, more hematopoiesis occurs in the marrow of the pelvis, cranium, vertebrae, and sternum (Jagannathan-Bogdan and Zon, 2013).

Fig. 1 Stem cell differentiation from bone marrow. Adapted from “Stem cell differentiation from bone marrow”, by BioRender.com (2021). Retrieved from <https://app.biorender.com/biorender-templates>.

Blood cell types, including RBCs, lymphocytes, and other cells, all originate from a hematopoietic stem cell (HSC). HSC have a cell surface marker known as CD34 and do not express lineage-specific markers. HSC generates two types of progenitor cells: one that generates lymphoid progenitors and the other that generates myeloid, erythroid, and megakaryocyte cells. Lymphoid progenitors become multiple precursors of T, B, or innate lymphoid cells such as natural killer cells (NK cells). On the other hand, myeloid precursors can be turned into erythroid, megakaryocytes, granulocytes, and monocytes (Fig. 1) (Jagannathan-Bogdan and Zon, 2013).

In addition to HSCs and developing cells, bone marrow also has a large number of long-lived plasma cells. These antibody-producing cells are produced in peripheral lymphoid tissues by antigen stimulation from B-lymphocytes and then migrate to the bone marrow (Pioli, 2019).

Secondary lymphoid organs

Lymph node

The lymph nodes, as one of the most important secondary lymphoid organs, are located in a regular and extensive network throughout the body. Lymph nodes are round or bean-shaped organs located at the junction of large lymphatic vessels. A capsule of connective tissue surrounds this organ and several lymphatic ducts enter or exit it. Each lymph node is composed of three distinct sections, including the cortex, the paracortex, and the medulla. B and T lymphocytes are present in different areas of the lymph nodes. The cortex and paracortex are where the B and T lymphocytes are located, respectively (Fig. 2). The paracortex is also rich in MHCII⁺ dendritic cells or interdigitating dendritic cells (IDC), which have the ability to pick up antigens and present them to T cells, therefore triggering T cell-mediated immune responses. The cortex possesses lymphoid follicles, and in fact, it is the site of humoral immune response in order to produce antibodies against antigens. The medulla is rich in plasma cells.

Antigens enter the lymph node through the afferent lymphatic vessel. Of course, large antigens are received by subcapsular macrophages and are presented to cortical B lymphocytes. This is the first step in antibody-mediated responses to these antigens. In response to antigens, an area called the “germinal center” is formed in the follicles. The germinal center contains active B lymphocytes and follicular dendritic cells (FDCs), and these are sites of significant proliferation of B cells, selection of B lymphocytes producing high-affinity antibodies, and production of memory cells and long-lived plasma cells (Liao and Padera, 2013).

Fig. 2 Lymph node structure and location of immune cells. Adapted from “Lymph Node Structure & Location of Immune Cells”, by BioRender.com (2021). Retrieved from <https://app.biorender.com/biorender-templates>.

Spleen

The spleen is the largest secondary lymphoid organ whose main function is to clear the blood of damaged cells, encapsulated bacteria, and old red blood cells. The spleen is one of the most important organs in the synthesis of antibodies, especially IgM against polysaccharide antigens. In addition, it is a place to store RBC, WBC and platelets. A capsule of connective tissue surrounds the spleen. The splenic parenchyma is anatomically and functionally divided into two important parts: the “red pulp,” which contains sinusoids, and the macrophages present in this part play an important role in clearing damaged cells and opsonized pathogens from the bloodstream; the other is “white pulp,” which is rich in lymphocytes and plays a role in triggering adaptive immune responses to specific antigens in the blood. The white pulp is made up of lymphatic tissue that includes the pale periaarteriolar lymphoid sheath (PALS) and lymphoid follicles. The PALS is rich in T lymphocytes and is similar to the paracortex of the lymph node.

The boundary between the white and red pulp is called the “marginal zone.” This region is made up of B cells, dendritic cells, and macrophages. B cells in this area are called marginal zone B cells (MZB) and function differently than B cells in the follicles (Lewis et al., 2019).

Mucosal associated lymphoid tissue (MALT)

These tissues are the lymphoid organs of the mucosal surfaces of the respiratory, gastrointestinal, and urogenital systems, which are divided into different types depending on their location, including Gut-Associated Lymphoid Tissue (GALT), Bronchus-Associated Lymphoid Tissue (BALT), and Nose-Associated Lymphoid Tissue (NALT).

MALT makes up more than 50% of the body’s lymph tissues. Most body antibodies, secretory IgA (sIgA), and most plasma cells are found in MALT. Gastrointestinal-Associated Lymphoid Tissue includes Peyer’s patches, the appendix, and tonsils.

The main areas of the GALT include small bowel Peyer’s patches, lymphoid follicles throughout the intestine, and mesenteric lymph nodes. Peyer’s patches are lymphoid communities that are surrounded by specialized cells known as “M cells.” These cells actively pinocytosis the macromolecules and transport them from the intestinal lumen to the subepithelial tissues. The intestinal lamina propria contains a variety of cells, including T and B lymphocytes, plasma cells, macrophages, eosinophils, and mast cells. Most lamina propria B cells are plasma cells that produce IgA. Macrophages, especially dendritic cells, are important antigen presenting cells of the lamina propria that play a role in the presentation of lipids and glycolipids to intraepithelial T cells (Cesta, 2006).

An overview of the innate and adaptive immune system

Innate immune system: Components and effector functions

Innate immunity is the first line of defense against pathogens that responds quickly to harmful agents or pathogens. The cellular and molecular components of the innate immune system are present and functioning even before infection. However, some of them, such as the complement system, become active when confronted with stimuli. Although innate immune responses are very effective in eliminating the stimuli in the early minutes after exposure, an efficient immune response requires the cooperation of the adaptive immune system (Tosi, 2005; Beutler, 2004). In this regard, the innate immune system has the ability to activate adaptive immunity through several mechanisms. In the following section we will discuss the components of the innate immune system.

Physical and chemical barriers

The barriers prevent pathogens from entering the body. The epithelial cells lining the respiratory, gastrointestinal, and genitourinary tracts, in addition to providing the tight junctions, can generate a considerable amount of “mucins.” Mucins are mucus-enriched glycoproteins that trap bacteria and impede their spread. Epithelial cells also provide a chemical barrier by generating antimicrobial agents (Schleimer et al., 2007). Chemical barriers against infection include:

1. *Lysozyme*: an enzyme that is found in abundance in secretions such as sweat and tears. Lysozyme is toxic to many pathogens and causes them to lyse. This enzyme is involved in the breakdown of the gram-positive bacteria's cell wall (Sukhithasri et al., 2013).
2. *The acidic pH of the stomach*: prevents the growth and colonization of many pathogens (Smith, 2003).
3. *Defensins*: small cationic peptides that contain two important types of alpha- and beta-defensins in humans. These peptides are produced by mucosal epithelial cells as well as leukocytes such as neutrophils, natural killer cells (NK), and natural killer T cells (NKT). Pant cell defensins are called “Crypticidins,” which are involved in eliminating pathogens in the intestinal lumen (Ganz and Lehrer, 1997; Ouellette and Selsted, 1996).
4. *Cathelicidins*: initially produced as a precursor protein that can be converted to two peptides with protective functions by the effect of microbial products and inflammatory cytokines. They have a toxic effect on a wide range of microorganisms and can also activate various leukocytes to eliminate the pathogen. The C-terminal piece of the cathelicidins is called LL-37 and has the ability to bind to the LPS and neutralize it (Roby et al., 2013).
5. *Lectins*: These are a group of antimicrobial proteins that act particularly against Gram-positive bacteria. They have a carbohydrate recognition domain (CRD) and bind to surface-exposed carbohydrate moieties of peptidoglycan to mediate bacterial death. Reg III is a mouse lectin produced by intestinal Paneth cells which binds to bacterial peptidoglycans. HIP/PAP is an example of a human lectin that causes bacterial death by creating a hole in the bacterial membrane (Breitenbach Barroso Coelho et al., 2018).
6. *Histatins*: these proteins are rich in histidine and found in saliva. Histatins are antibacterial and antifungal proteins that are also involved in wound healing (Edgerton and Koshlukova, 2000).

Innate immune cells: Quickly activated and respond as the first line of defense against infections

The innate immune system contains a variety of cells that can detect and respond quickly to pathogens. These cells include monocytes, macrophages, neutrophils, eosinophils, basophils, mast cells, dendritic cells, NK cells, natural killer T (NKT) cells, and innate lymphoid cells (ILCs). Cellular components of the innate immune system serve a variety of functions aiming to eliminate the pathogen, including inhibition of pathogen entry into the body, antigen capturing by phagocytosis or pinocytosis, killing the pathogens through cytotoxic mediators, and activating the adaptive immune system.

Monocytes and macrophages

These cells are considered professional phagocytes and respond to stimuli via several functions, including antigen presentation and T cell activation, cytokine production, antibody-dependent cell cytotoxicity (ADCC), tissue repair, and regeneration. Monocytes are present in the bloodstream and can move to various body tissues, where they develop into macrophages and myeloid-derived dendritic cells. Interestingly, monocytes are involved in both inflammatory and anti-inflammatory responses. Classical monocytes play an important role in inducing inflammatory responses through phagocytosis and ADCC. On the other hand, non-classical monocytes are more involved in homeostasis maintenance (Sampath et al., 2018). Similarly, two types of macrophages known as “M1 or classically activated macrophages” and “M2 or alternatively activated macrophages” exert pro-inflammatory and anti-inflammatory functions, respectively. M1 macrophages express a number of markers, including Major Histocompatibility Complex II (MHC II), CD80 (B7.1), CD86 (B7.2), and a number of toll-like receptors involved in pathogen recognition and immune response activation. These cells secrete important pro-inflammatory cytokines and chemokines, including IL-1, IL-6, TNF- α , IL-12, CXCL9, and CXCL10. On the other hand, M2 macrophages produce anti-inflammatory cytokines such as IL-10 and TGF- β (Yao et al., 2019).

Dendritic cells (DCs)

These cells are widely found in lymphoid, epithelial, and parenchymal tissues. DCs play a crucial role in the initiation and polarization of immune responses through several functions. DCs in an immature state are present in the blood and after activation, they migrate to the lymph nodes where they interact with T and B lymphocytes to trigger adaptive immune responses. These cells are considered as the professional antigen presenting cells (APCs) so that they have the potential to uptake the antigens by phagocytosis or pinocytosis, processing the antigen and presenting them to T cells, leading to adaptive immune response activation. Therefore, DCs are known as the most important cells, playing an effective role in the relationship between innate and adaptive immunity. DCs express a variety of receptors, including TLRs, to recognize pathogens and microbial components (Hemmi and Akira, 2005; Cerboni et al., 2013).

Immature DCs have a high antigen uptake and processing capacity. Antigen processing by DCs induces high levels of MHC II molecules and co-stimulatory molecules on DCs which are essential for T cell activation. Moreover, active DCs produce a high level of pro-inflammatory cytokines that play an important role in recruiting other leukocytes to the inflammatory site as well as polarization of T lymphocytes. IL-12 is one of the most important cytokines involved in the formation of T lymphocyte responses.

Interestingly, antigen-activated DCs express high levels of chemokine CCR7, which binds to the CCL19 expressed on the high endothelium venule (HEV), leading to the entry of DCs into the lymph node, where they can present antigens to the T cells (Patente et al., 2019).

Different populations of DCs with distinct properties and activities have been found. The two most common DC subtypes are as follows:

1. *Conventional (cDCs)*: They have been found to release pro-inflammatory cytokines and have a high ability for antigen uptake and presentation to naive CD4⁺ T cells (Haniffa et al., 2013).
2. *Plasmacytoid dendritic cells (pDCs)*: They are well recognized for producing type I interferon (IFN-I) during viral infection, but they also have other functions like stimulating T and NK cells and producing pro-inflammatory cytokines (Swiecki and Colonna, 2015).

Neutrophils

These cells develop in the bone marrow under the influence of IL-3, G-CSF, and GM-CSF and then enter the bloodstream. Neutrophils make up 60–70% of peripheral blood leukocytes and, as a professional phagocyte in the peripheral blood, they play a role in defense against extracellular pathogens. These cells are one of the most important innate immune cells involved in response to encapsulated bacteria and fungi (Uribe-Querol and Rosales, 2017). In general, neutrophils can be divided into two groups based on phenotype and function (Wang et al., 2018):

1. *N1 neutrophils*: These cells perform pro-inflammatory functions by producing important inflammatory mediators and they have a high phagocytic potential.
2. *N2 neutrophils*: By producing mediators such as VEGF, IL-1ra N2 neutrophils are more involved in inducing an immunosuppressive microenvironment and therefore resolution of inflammation.

Neutrophils are recruited to the inflammatory site by cytokines and chemokines. Neutrophils are the first cell to be called to the inflammatory site and are an indicator of acute inflammation. An increase in neutrophils in the peripheral blood, known as “neutrophilia,” is caused by various factors such as bacterial infection, stress, hypoxia and even strenuous exercise (Tahir and Zahra, 2021). On the other hand, a decrease in neutrophils or neutropenia is seen in conditions such as chronic infections, leukemia, cytotoxic drugs, aplastic anemia (Justiz Vaillant and Zito, 2021).

Neutrophils have important receptors, including complement receptor-1 (CR1), CR3, and receptors for IgG and IgA that help these cells in the process of phagocytosis (Futosi et al., 2013). Active neutrophils are able to produce many inflammatory cytokines, including IL-12, IL-1, IL-6, IL-18, IL-8, TNF- α , and GM-CSF (Tecchio et al., 2014). These cells are short-lived phagocytes that die shortly after phagocytosis. Dead or dying neutrophils are the majority of pus. Neutrophils possess granules that contain antimicrobial proteins (Cowland and Borregaard, 2016). These granules include the following:

1. *Primary granules*: account for 10–20% of neutrophil granules. Primary granules contain antimicrobial proteins, including myeloperoxidase, lysozyme, and defensin. Besides, it contains proteases such as elastase, proteinase, cathepsin G.
2. *Secondary granules*: account for 80–90% of neutrophil granules. Lysozyme, gelatinase, lactoferrin, and B12-binding proteins are some of the proteins in these granules.
3. *Tertiary granules (gelatinase)*: These granules contain gelatinase (MMP9), arginase 1, and MMP25.

Exocytosis occurs when neutrophils release their granules in response to numerous stimuli such as microbial components or elevated intracellular Ca²⁺ levels, resulting in pathogen death. A lack of neutrophil-associated granules makes individuals more susceptible to Gram-positive or Gram-negative bacterial infections (Kumar and Sharma, 2010).

Another important function of neutrophils is a process known as NETosis. This process is a type of cell death distinguished by the release of decondensed chromatin and granular components into the extracellular environment, resulting in bacterial degradation. By generating neutrophil extracellular traps (NETs), neutrophils can defend against infections (Kumar and Sharma, 2010).

Basophils, mast cells, eosinophils

These cells have certain characteristics in common. All three cells have granules rich in antimicrobial mediators. These cells are involved in the defense against worms and parasites and play a role in the pathogenesis of allergic diseases.

Basophils develop in the bone marrow and then enter the bloodstream. Basophils account for less than 1% of peripheral blood leukocytes. These cells are involved in defending against parasites and causing immediate allergic reactions. Basophils have granules containing histamine, heparin, and serine proteases which play an important role in inducing inflammatory mechanisms in hypersensitivity reactions including asthma, anaphylaxis, and allergic rhinitis. Basophils have the potential to promote Th2 responses through producing IL-4 and IL-13 cytokines. Besides, they can produce other mediators, including leukotrienes and prostaglandins (Chirumbolo et al., 2018).

Mast cells develop in bone marrow under the influence of a cytokine called Stem Cell Factor (or c-Kit ligand). Mast cells are not normally present in the bloodstream, they are mostly found on the skin, in mucosal membranes, and in the vicinity of blood vessels. Similar to basophils, these cells are predominantly involved in allergic reaction pathophysiology. Besides, mast cells have critical roles in the immune response to bacterial and parasite diseases. Like basophils, these cells have high-affinity membrane receptors for IgE antibodies (Fc ϵ RI) (Abraham and Arock, 1998).

In summary, when B cells identify and uptake an allergen, the presentation of these allergens to T cells leads to the differentiation of Th2 cells, which help the B cell to make IgE. These antibodies bind to their receptors, FcεRI, on the basophil and mast cell surfaces. These cells are called sensitive cells at this point. Subsequently, re-entry of the allergen into the body leads to cross-linking of basophil and mast cell surface IgEs by the allergen. As a result, signaling pathways are induced that lead to the activation and degranulation of these cells. Granules contain storage substances such as histamine, heparin, kinase, tryptase, or mediators that are made after cell stimulation, such as IL-3, IL-4, IL-5, IL-13, IL-9, or lipid mediators such as leukotrienes, prostaglandins, thromboxane, and platelet activating factor (PAF). Consequently, the release of these granules leads to the appearance of allergy symptoms (He et al., 2013).

Eosinophils develop in the bone marrow under the influence of GM-CSF, IL-5, and IL-3. In addition to the blood, eosinophils are present in peripheral tissues, especially in the lining of the gastrointestinal tract, respiratory tract, and urogenital tract. These cells have very weak phagocytic potential. Instead, these cells are the most important cells in killing worms, including schistosomiasis, through ADCC. These cells bind to IgG-coated and IgE-coated parasites via FcγR and FcεR receptors, respectively. Subsequently, this stimulates the release of mediators from eosinophil granules. In general, these cells kill the worms, particularly by FcεRI and IL, especially through the ADCC. Besides, due to their role in tissue repair, eosinophils can be involved in establishing homeostasis (Mukai et al., 2016; Weller and Spencer, 2017).

Eosinophils are able to make metabolites such as leukotrienes and prostaglandins after stimulation. Leukotrienes are involved in mucus secretion, vascular permeability, and prolonged bronchospasm. Cytokines (e.g., IL-5, IL-3, IL-4, IL-8, IL-1, IL-13, IL-25, TNF-α), growth factors (e.g., GM-CSF, TGF, VEGF, and NGF), as well as chemokines (e.g., CXCL1, CXCL5, CXCL8, CXCL9) are also important mediators that Eosinophils secrete after stimulation. In addition, these cells contain granules that release their contents in defense against worms and parasites (Shamri et al., 2011). This content includes the following:

1. Major Basic Protein (MBP).
2. Eosinophil Cationic Protein (ECP).
3. Eosinophil Peroxidase (EPO).
4. Eosinophil-Derived Neurotoxin (EDN).

Natural killer (NK) cells

These cells originate from the lymphoid lineage in the bone marrow. IL-7 and IL-15 cytokines play an important role in the development and survival of NK cells. They are known as large granular lymphocytes (LGL) and account for 5–15% of blood and spleen lymphocytes. Although they originate from the lymphoid lineage, they often do not express B and T cell markers, so they are known as non-B, non-T lymphocytes. These cells are the first lymphocytes involved in innate defense against intracellular infections, especially virus-infected cells and cancerous cells (Vivier et al., 2008).

The formation of an immunological synapse between the NK cell and the target cell is required for the cytotoxic response of the NK cell. These cells bind to the surface antigens of the virus or tumor cells through their receptors and exert their cytotoxic activity. One of the most important receptors involved in the NK cytotoxic process is CD16 (FcγRIII). This receptor binds to cells coated with IgG antibodies, resulting in the release of the cytotoxic granules of the NK cell, killing the target cell through ADCC. However, in addition to NK cells, macrophages, neutrophils, and eosinophils are also able to mediate ADCC. NK granules contain lethal mediators such as perforin and granzyme. Perforin polymerization on the cell membrane of target cells creates pores that allow granzymes to enter the cells. Granzyme is a serine protease which activates the enzymes known as “caspases,” resulting in the induction of cell death or “apoptosis” in target cells. Apoptosis of the target cells can also occur through other receptors such as the TNF receptor (TNFR) and the Fas receptor (Topham and Hewitt, 2009; Sonar and Lal, 2015; Thorburn, 2004).

In general, NK cells can be divided into two categories based on markers, each of which has different functions. CD16^{High}CD56^{Low} NK cells have high levels of perforin, therefore they have more cytotoxic effects. On the other hand, CD16^{+/−}CD56^{High} NK cells are distinguished by low amounts of perforin and are extremely proficient in cytokine generation. Once activated, NK cells release a variety of cytokines and chemokines, including IFN-γ, TNF-α, IL-2, granulocyte macrophage colony-stimulating factor (GM-CSF), CCL1-CCL5, and CXCL8 (Paul and Lal, 2017).

Helper innate lymphoid cells (ILCs)

These cells originate from the lymphoid precursor in the bone marrow. They are morphologically similar to lymphocytes. In addition, the function of ILCs is very similar to that of helper T cells. However, they lack the T cell receptor, costimulatory molecules, as well as CD3, and their stimulation is not dependent on the MHC molecule.

These cells include heterogeneous populations and are present in many tissues, including lymphoid tissues, peripheral organs such as the lungs, dermis, liver, and small intestine and play a vital role in mucosal immunity and tissue homeostasis. Three categories of helper ILCs are recognized based on their similarity to helper T cell subtypes in terms of transcription factor and cytokine production (Mathä et al., 2021a,b; Vivier et al., 2018).

1. ILC1s:

These cells produce IFN-γ and TNF-α against intracellular pathogens in the presence of IL-12, IL-15, and IL-18. ILC1s express the transcription factor T-bet and need IL-15 and IL-7 for their development and function. This group is thought to be responsible for defending against intracellular pathogens such as tumors and viruses. Unlike NK cells, these cells lack granzyme B and perforin. These cells also participate in the pathogenesis of inflammatory bowel and lung diseases (Fuchs et al., 2013).

2. ILC2s:

These cells develop under the influence of cytokines such as IL-25, IL-33, and TSLP and produce IL-5 and IL-13. This group expresses the transcription factor GATA3. ILC2 cells induce Th2 responses through IL-4 production. In addition, IL-13 produced by ILC2s plays an important role in the removal of intestinal worms by inducing goblet cell division, eosinophilia, and contraction of colon smooth muscle cells. Pathologic and protective functions of ILC2s have been reported in a variety of human disorders, including fibrosis, asthma, atopic dermatitis, as well as infections (Mathä et al., 2021a,b).

3. ILC3s:

ILC3s play a critical role in the immune response to extracellular bacteria and fungus. This group expresses the transcription factor ROR γ t. In response to IL-23 and IL-1, they generate IL-22 and IL-17, which stimulate Th17 responses and neutrophil recruitment. In addition, these cells contribute to the upregulation of antimicrobial peptides and the improvement of barrier integrity, particularly in the gut, by producing IL-22 (Aujla et al., 2008; Sugimoto et al., 2008; Zheng et al., 2008).

Effector mechanisms of the innate immune system

Identify the stimulus

To generate appropriate responses, the innate immune system must recognize the stimulus properly. A variety of innate immunity receptors have been described, each identifying “pathogen-associated molecular patterns” (PAMP) or “damaged-associated molecular patterns” (DAMP). PAMPs are specific to pathogenic microorganisms and are not present in mammalian cells, such as viral RNA, lipopolysaccharide (LPS) of Gram-negative bacteria, and peptidoglycan of bacterial cell wall. DAMPs may be generated by cellular damage caused by infection or by non-infectious agents or other causes such as chemical toxins, burns, and trauma. Heat shock proteins (HSPs), high mobility group box 1 (HMGB1), urate crystals, and cholesterol are examples of DAMPs. PAMPs and DAMPs can be detected by non-specific receptors known as “pattern recognition receptors”, or PRRs, which are found in immune cells’ sub cellular compartments (e.g., within phagocytic vesicles, in the cytoplasm or cell surface) (Mogensen, 2009).

Several types of PRRs have been identified, including:

1. Toll-Like Receptors (TLR).
2. Nucleotide-binding Oligomerization Domain (NOD).
3. Leucine Rich Repeats-containing receptors (NLR).
4. Retinoic acid-inducible gene 1 (RIG-1)-like receptors (RLR).

By binding to the PAMPs or DAMPs, PRRs induce the signaling pathway, which in turn enhances antimicrobial and proinflammatory functions in the cells expressing these receptors. Other innate immune receptors involved in identifying microbial components and inducing inflammatory responses against pathogens include:

1. Scavenger receptor (SR): Most often expressed on monocytes, macrophages, and dendritic cells, it includes various types such as CD163, CD36, and Macro. They bind to lipids, carbohydrates, oxidized or acetylated LDL. These receptors are effective in phagocytosis of microorganisms and are involved in clearing tissue of apoptotic cells, altered lipoproteins, LPS and lipoteichoic acid (Zani et al., 2015).
2. CD14: It is known as the LPS receptor and can bind to lipid A. It is expressed by most cells except endothelial cells. This receptor plays an important role in inducing an effective response to LPS by TLR4 (Viriyakosol et al., 2000).
3. C-type lectin receptors (CLRs): These receptors detect carbohydrates on the surface of microbes and facilitate the phagocytosis of them. There are a number of receptors in this family, including mannose receptor (MR), DC-SIGN, and Dectins (Yan et al., 2013).
4. Complement receptors (CRs): In addition to binding to complement components and inducing inflammation, these receptors act as opsonin receptors and stimulate phagocytosis or intercellular adhesion. For example, CR3 can be bound to LPS or to the complement components C3b and iC3b (Vorup-Jensen and Jensen, 2018).

Effector mechanisms

Several effector functions are defined by components of the innate immune system, including pathogen killing by phagocytosis or cytotoxic mediators, recruitment of the other immune cells by production of inflammatory mediators, and antigen processing and its presentation to adaptive immune cells. In the following, we will review the most important executive mechanisms of the innate immune system.

Phagocytosis

It is a process in which the pathogen is first surrounded by a phagocytic membrane and is killed in the phagosome vesicle under acidic conditions (Fig. 3). The most important phagocytic cells are neutrophils, monocytes, and macrophages. However, dendritic cells also have high phagocytic ability and act as antigen carriers to secondary lymphatic organs. Eosinophils, basophils, and mast cells are also able to perform phagocytosis with less power (Rabinovitch, 1995).

Fig. 3 Schematic diagram of phagocytosis. CR: complement receptor; FcγR: Fc gamma receptor; IgG: Immunoglobulin G. Created by BioRender.com (2021).

Although phagocytosis can occur in the absence of opsonins, antigens coated with opsonins are more easily phagocytosed. In this regard, the opsonized particular antigens with complement components (e.g., C3b) and antibodies bind to the complement receptor (CR) and the Fc receptor (FCR), respectively, and eventually, by contracting actin and myosin and forming a membrane around the antigen, phagosomes are formed. Subsequently, by phagosome and lysosome fusion, phagolysosome is produced and antigen is digested inside the phagolysosome. Receptors that are able to directly detect a wide range of microorganisms without the involvement of opsonins include scavenger C-type lectin receptors, scavenger receptors, and TLRs (Freeman and Grinstein, 2014).

Complement system

The activation of the “complement system” is another important effector mechanism of the innate immune system. Over 30 soluble and cell surface proteins make up this system. The complement system can be activated via three major pathways, including classical, alternative, and lectin pathways (Ghebrehiwet, 2016). Activation of these pathways eventually leads to events including pathogen destruction, increased recruitment of inflammatory immune cells, and enhanced phagocytosis. The “classical pathway” is activated by the immune complexes of antigen-antibody, which consists of antibodies (IgG1 or IgM) attached to the cell surface of pathogens. In this pathway, the C1 complex (C1q, C1r, C1s) binds to the Fc region of antibodies. C1s is a serine protease that cleaves C4 and C2 into C4a, C4b and C2a, C2b, respectively, when activated. C4b and C2a then form the C4bC2a complex, which interacts with the pathogen surface. The C4bC2a complex functions as a “C3 convertase” enzyme, cleaving C3 into C3a and C3b fragments.

The C3b fragment attaches to the microbial surface covalently, and when linked with C4bC2a, it forms the C5 convertase complex (C4bC2AC3b), which converts C5 to C5a and C5b. C5b binds to the microbial surface, causing other components such as C6, C7, C8, and C9 to become activated. Finally, polymerization of C9 on the pathogen surface leads to the creation of numerous pores known as the “membrane attack complex,” or MAC, which can lyse the pathogen directly.

The “lectin pathway” is similar to the classical pathway; however, it does not require antibodies to activate. PRRs such as mannose-binding lectin (MBL) and ficolins identify the carbohydrates on the microbial surface. MBL forms a complex with the MBL-associated serine proteases (MASPs)-1, -2, and -3, whose activation results in the cleavage of C2 and C4, and the subsequent production of the C3 convertase (C4bC2) of both classical and lectin routes.

The spontaneous hydrolysis of C3 into C3a and C3b activates the “alternate pathway.” C3b binds to the microbial surface in the presence of microbial infection. As a result of the interaction of B and D factors with C3b, further C3 cleavage occurs, resulting in the formation of alternative route C3 convertase (C3bBb) and C5 convertase (C3bBbC3b). Properdin is a protein that helps to stabilize alternative pathway convertases and promotes alternative activation.

ADCC

Another important function resulting in pathogen elimination is ADCC, which was previously described in NK cell functions. This process requires immune cells expressing the Fc receptor as well as a target antigen coated by the antibody. As previously mentioned, immunoglobulin G (IgG) and its receptor named FcγRIII (CD16) play an important role in ADCC activation (Mielke et al., 2019).

Antigen presentation

This process can be considered as a key mechanism linking the innate and adaptive immune systems. As mentioned earlier, adaptive immunity is required to establish a proper response against the pathogen. The presentation of antigen by “Antigen presenting cells” or APCs to T cells is one of the vital events in T cell activation. In general, APCs are cells that are able to perform antigen recognition and uptake, antigen processing, loading the peptide epitopes on the MHC molecules, and finally antigen presentation in the form of the MHC:peptide complex to T lymphocytes. Dendritic cells, macrophages, and B cells are considered as the professional APCs (DiLillo et al., 2011; Katz, 1988).

MHC molecules are membrane glycoproteins which are composed of two types, including MHC class I and MHC class II which in turn involve in presentation pathway I and II, respectively. The most important difference between pathway I and II is the source of peptides that are presented. On the presentation pathway by MHC I, peptides derived from proteins synthesized in the cytoplasm (such as viral proteins) are presented to cytotoxic T cells (CTLs). MHC class II molecules are involved in the presentation of peptides derived from proteins in intracellular vesicles (such as peptides derived from pathogens living in macrophage vesicles or internalized by phagocytes) to Th1 or Th2 cells. Upon recognizing their targets, the effector T cells are stimulated to produce and release various mediators to kill the target cells (CTLs) or help to recruit other effector cells (Th cells) (Blum et al., 2013).

Adaptive immune system: Components and effector functions

B lymphocytes and antibodies: The main players in humoral immunity

B lymphocytes are one of the specific immune cells that make up the humoral immunity arm. As described in the organs section, these cells develop in the bone marrow and fetal liver, and their final differentiation occurs in the secondary organs (e.g., lymph nodes or spleen) after stimulation with antigen. These lymphocytes normally circulate between the blood, lymph and organs. Upon exposure to antigens, B lymphocytes proliferate and differentiate into memory cells and plasma cells. Memory cells are involved in the secondary response to antigen, and plasma cells are antibody-producing cells. B lymphocytes possess membrane immunoglobulins (mIg) for specific antigen recognition and uptake (DiLillo et al., 2011).

Antigen recognition and B cell activation

B lymphocytes recognize the antigens through the B cell receptor (BCR) complex, which consists of two important parts (Pleiman et al., 1994):

1. The portion of the protein that binds to the antigen known as BCR
2. Signal transmission units include CD79a (Igα) and CD79b (Igβ), molecules which are known as first signals for B cell activation.

Once the B cell is activated, the second signal, which includes the interaction between CD40 (expressed on B cells) and CD40L (expressed on T cells), is activated. In addition, a complex called the co-receptor on the B cells plays a vital role in B cell activation. This complex consists of three important molecules, including CD21, CR2, and CD81 (TAPA-1).

Types of B cells

B1 and B2 cells are two subclasses of B cells that have diverse phenotypes and functions. B1 cells are mostly located in the peripheral organs and are rarely found in the blood. They are extremely capable of producing natural antibodies in the absence of any infections. These cells are abundant in the fetus and early infancy. B2 cells are classified into two types: B follicular (BFO) and B marginal zone (BMZ). BFOs are the most common type of B cell in circulation and they produce the majority of antibodies during an infection. BMZs are found largely in the spleen’s marginal zone and play a role in defense against blood-borne infections (Pieper et al., 2013).

Antibodies: The mediators of humoral immunity

Antibodies are glycoproteins found in body fluids such as whole blood, serum, or plasma, as well as extracellular fluids. These molecules are the products of plasma B cells and bind specifically to antigens. An antibody molecule has a Y-shaped structure and consists of two similar light chains (L) and two similar heavy chains (H) (Forthal, 2015). In general, immunoglobulins are divided into five classes based on differences in heavy chain structure, including:

IgG: It is structurally a monomer antibody containing two heavy and two light chains. This antibody makes up 60–70% of all serum immunoglobulins and has the longest half-life. This antibody is the strongest antitoxin. IgGs are often produced in the second response to an antigen. IgG1 and IgG3 antibodies are the most important opsonins and are involved in ADCC, especially by the NK cell.

IgA: It is found in various forms of monomer, dimer, trimer, etc. It is the most important antibody in mucous secretions and its key function is mucosal defense. sIgA, a secretory dimer form, is found in gastrointestinal, genital, respiratory, saliva, and tear secretions. Serum IgA can activate complement through an alternative pathway.

IgM: It makes up 10% of serum antibodies and is often found in the form of pentamer in the serum. The monomer IgM is present on the cell membrane of the B lymphocyte. It plays an important role in the identification of carbohydrate antigens. This antibody is involved in stimulating the classical pathway of the complement system.

IgE: This antibody has a monomeric structure and has a short half-life. Of course, it is found on the surface of basophils and mast cells with a long half-life. This antibody plays a major role in type I hypersensitivities.

IgD: This antibody is found in monomer form on the membrane of the B lymphocytes. It accounts for less than 1% of total serum immunoglobulins.

IgG and IgA can be divided into subclasses based on differences in biological activity or other factors such as structure, electrophoretic motion, and hinge length. There are four IgG subclasses, including IgG1, IgG2, IgG3, and IgG4. IgA1 and IgA2 are two subclasses of IgA.

Antibodies are bi-functional molecules; they bind to antigens via an antigen binding site located in the amino terminal (N-terminal) of the antibody. This process is also known as “neutralization”, through which antibodies neutralize pathogens or their toxic products by binding to them and thus preventing them from entering cells. On the other hand, antibodies exert their biological effects via the stem of the Y structure, which is referred as “fragment crystallizable region” or Fc. The most important biological functions of antibodies are the induction of ADCC and activation of the complement system (Fig. 4).

Importantly, different cytokines have distinct effects on B cell activation and antibody production. In this regard, IL-5 is involved in the differentiation of IgA-producing plasma cells and mucosal immunity. IL-2 enhances antibody production by proliferating and stimulating B lymphocytes. In humans, IFN- γ cause antibody class switching to IgG1 and IgG3. These antibodies stimulate the complement system and ADCC. IL-4 is involved in the production of IgE, which plays an important role in hypersensitivity type I and in defense against parasites. IL-6 is involved in the differentiation of plasma cells and IgA production.

T lymphocytes: The main players of cellular immunity

T lymphocytes develop in the thymus and make up approximately 50–70% of peripheral blood lymphocytes. These cells, like B lymphocytes, have specific antigen receptors known as T cell receptors (TCRs) and therefore interact specifically with the target cell. Importantly, the function of these cells depends on the MHC molecules and they respond only when the antigen is presented to them by the MHC. In other words, unlike B cells, T cells are not able to directly detect antigens unless the antigen is associated with the MHC molecule. In this section, we will review how the T cell is activated, its effector functions, and the types of T cells.

Antigen recognition and T cell activation

Similar to B cells, T cells have an antigen-recognizing complex and costimulatory molecules (Griesser and Mak, 1994). TCR acts as an antigen recognition molecule, and CD3, along with TCR, is involved as the first signal in signal transduction and stimulating T cells (Fig. 5). CD28 is expressed as the second signal on T cells. It has a homodimeric structure that binds to B7 molecules (B7–1 and B7–2) on APCs. Involvement of CD28 leads to the activation of several signaling pathways, which eventually leads to the activation of the T cell. Interestingly, when the frequency of B7 is low, such as when APCs are resting or after pathogen elimination, a molecule called CTLA4, which has a higher affinity for B7, interacts with B7 molecules, resulting in diminished T cell responses and establishing homeostasis (Kosmaczewska et al., 2001).

The formation of synapse between the T cell and the APC is required for proper T cell activation. In this region, interactions occur between molecules on the surface of T and APC cells, and cytokines and mediators are transported more rapidly. IL-1, IL-12, and IL-15 are the first cytokines secreted by APC resulting in T cell stimulation. Once activated, T cells produce cytokines including IFN- γ , IL-2, IL-4, and IL-5 which in turn enhance the APC or T cell responses (Malissen et al., 2014).

The effector mechanism of T lymphocytes

In general, T cells have important functions, including antigen recognition, responding to intracellular antigens such as tumor or virus antigens, helping to produce antibodies from B cells, and regulating immune responses.

Some pathogens, such as viruses, parasites, and bacteria, require entry into cells where they are not identified by antibodies. These intracellular infections are eliminated by T cells. T cells are classified into two types: helper T cells (TH) and cytotoxic T cells (CTL) (Chaplin, 2010).

Helper T cells

Th cells express CD4 marker and they are involved in helping other immune cells in responding to pathogens especially through producing cytokine including $\text{IFN}\gamma$, IL-2, and $\text{TNF-}\alpha$. They identify peptide antigens provided in the form of “MHC II: peptide complexes” by APCs. Th1 and Th2 are the major subsets of the helper T cells. However, other subsets such as Th17, Th22, Th9, Th25, etc. have also been identified which play important roles in immune responses (Romagnani, 1991; De Sousa and Quaresma, 2018; Maddur et al., 2012; Jia and Wu, 2014).

Th1 cells

These cells play a vital role in preventing intracellular bacterial infections such as *Mycobacterium tuberculosis* and *Mycobacterium leprae*. These cells are the most important source of IL-2 and $\text{IFN}\gamma$ cytokines. IL-12 and $\text{IFN-}\gamma$, which can be produced by APCs and NK cells, respectively, play an important role in the differentiation of Th1 cells. These cytokines activate transcription factors T-bet, STAT1, and STAT4 and are considered to be the main regulators of Th1 cells (Constant and Bottomly, 1997).

Dendritic cells and macrophages are the most important cells that present antigen to Th1 cells. Th1 helps kill phagosomal antigens by stimulating macrophages. In this regard, Th1 stimulates the activation of reactive oxygen intermediates (ROI) and nitric oxide (NO) in phagocytes by producing $\text{IFN-}\gamma$, and thus plays an effective role in the death of phagocytosed antigens (Fig. 6). Other Th1 activities include increase macrophage infiltration to the sites of infection, promote the cytotoxic T cells and NK cells responses, induce B cell responses to make opsonizing antibodies and complement-activating antibodies importantly IgG1 and IgG3.

Th2 cells

Th2 cells play a key role in the eradication of extracellular bacteria and parasitic helminth infections through activating B cells (Constant and Bottomly, 1997). They produce a variety of cytokines including IL-4, IL-5, IL-9, and IL-13 which have an important role in controlling the extracellular helminth infections such as *Schistosoma mansoni* (Oliphant et al., 2011). Besides, they are involved in pathogenesis of hyper sensitivity type I by inducing the production of IgE antibodies.

B cell is considered as the APC that present antigen to Th2 cells. Th2 cytokines, including IL-4 and IL-5, are important mediators in the proliferation and differentiation of B cells and the production of IgA and IgE. Besides, IL-4 activates the transcription factor STAT6 which triggers the development of Th2 cells. STAT6 is also leads to the induction of GATA3 expression. GATA3 is the main regulator of Th2 differentiation. Th2 cytokines also induce recruitment and activation of the inflammatory cells including basophils, mast cells, and eosinophils.

Cytotoxic T cells (CTLs)

Cytotoxic T cells are an important subset of T cells that respond to intracellular infections such as viruses and malignant cells. These cells have CD8 molecules on their cell surfaces and can regulate the infection by killing infected cells directly. They recognize peptide antigens provided in the form of “MHC I: peptide complexes” by APCs (Fig. 7) (Henkart, 1997).

By recognizing the target antigen by the TCRs, T cells initiate target cell apoptosis. The main mechanism of killing the target cell by CTL is the release of cytotoxic mediators including perforin and granzyme. CTL cytotoxic granules are similar to NK cells and kill the target cell by creating a pore in it. There are other pathways for target cell apoptosis by CTLs, including FasL (or CD178, expressed

on active T cells) interaction with Fas (or CD95, expressed on cancerous cells or virus-infected cells), which leads to "Caspase 8" stimulation and target cell apoptosis. Another pathway is interaction between TNF and its receptor, TNFRI or CD120a, causing Caspase 8 stimulation and apoptosis of target cell. TNF is produced from various cells, including CTL, NK, and Th1.

Abbreviations

APRIL	A proliferation-inducing ligand
BAFF	B cell-activating factor
BLNK	B cell linker protein
CLIP	Class II-associated invariant chain peptide
ICOS	Inducible T-cell costimulatory
LAT	Linker of activated T cells
PLCγ1	Phospholipase Cγ1
RAG	Recombinase activating gene
SCID	Severe combined immunodeficiency
SLP-65	SH2-binding leukocyte phosphoprotein of 65 Kd
SLP-76	SH2-containing leukocyte protein 76 Kd

TACI	Transmembrane activator and CamL interactor
TAP	Transporter associated with antigen processing
TREC	T-cell receptor excision circle
ZAP-70	Zeta-Associated protein, 70 Kd

Introduction

It has long been believed that innate immune system is non-specific, non-selective and the range of common pathogenic molecular patterns (PAMPS) it can recognize is limited. The extremely high variability of antigenic epitopes as well as the ability of pathogens to rapidly switch their antigenic phenotype has led to the counter-evolution of the adaptive immune response (Flajnik and Kasahara, 2010). The cells of innate immune system continually survey the environment and recognize the pathogens via PAMP-recognition receptors (PRRs) which are all encoded in the germline genome. This is in contrast to the lymphocytes of adaptive immune system that can recognize antigens through diverse, selected antigen-specific receptors that are generated by somatic DNA re-arrangement (Market and Papavasiliou, 2003). After initial exposure to pathogen, memory lymphocytes expressing pathogen-specific receptors are established, providing immunological memory and the capability for rapid and efficient counteract against subsequent exposure. After developing in the primary lymphoid organs (i.e., thymus and bone marrow), mature B and T lymphocytes migrate to secondary lymphoid organs where they can populate in distinct zones to capture and recognize their cognate antigens. Upon antigen-specific recognition, the lymphocytes are activated and differentiated into antigen-experienced effector cells. These cells exert their effector functions through either antibody production (for B cells) or supporting immune responses via production of cytokines or by directly killing virus-infected cells (for T cells). Interaction of antigen presenting cells (APCs) with T cells bridges innate and adaptive immune responses (Palm and Medzhitov, 2009; Iwasaki and Medzhitov, 2015). For example, APCs in concert with the molecules produced during innate immune reactions (e.g., cytokine and complement fragments) provide activation signals for T and B cells. Activated antigen-experienced lymphocytes can circulate in the body and home to the initial site of infection to exert their effector functions. This trafficking is tightly regulated by differential expression of adhesion molecules and chemokine receptors on lymphocytes (Jalkanen and Salmi, 2019). This article describes the principal mechanisms of lymphocyte development, activation and differentiation into various subsets, and ends with a discussion of how effector lymphocytes give rise to memory cells. An emphasis is also placed on the cell- and antibody-mediated immunity.

Types of adaptive immunity

General features

Innate immunity constitutes the first line of defense against invading pathogens. Innate immune responses are restricted to the recognition of specific structures that are conserved within a class of microbes, termed pathogen-associated molecular patterns (PAMPs). The nonclonotypic receptors of the innate immune system that evolved to recognize PAMPs are called pattern-recognition receptors (PRRs). However, many pathogens have evolved to resist innate immunity. Defense against such pathogenic microbes needs the more robust and specialized mechanisms of adaptive immunity (Flajnik and Du Pasquier, 2004). Although adaptive immunity is much slower to respond to threats, antigen-specific lymphocyte clones detect and respond to both microbial and nonmicrobial antigens. The ability to distinguish fine antigenic differences, also known as specificity, and the capacity to respond more powerfully to repeated encounters to the same antigens, also known as memory, are the another distinctive features of adaptive immunity (Table 1). Another cornerstone of the both adaptive and innate immunity is the recognition of “self” versus “non-self” (Hedrick, 2004). Although innate and adaptive immune responses are distinct arms of the immune system, both of them constitute an integrated host defense system that involves many cells and molecules which are function co-operatively (Iwasaki and Medzhitov, 2015).

Table 1 Comparative features of innate and adaptive immunity.

Feature	Innate immunity	Adaptive immunity
Specificity	Limited; only PAMPs	High; PAMPs+ nonmicrobial antigens
Specialization	No	Yes
Clonality	No	Yes
Diversity	Limited; germline encoded	Extensive; receptors are generated by somatic recombination of gene segments
Reactivity against self	No	No
Contraction and homeostasis	No	No
Memory	No	Yes

Phases of adaptive immune responses

The unique components of adaptive immunity are lymphocytes and their secreted products, such as cytokines, cytolytic molecules and antibodies. These lymphocyte-derived molecules in harmony with different components of innate immune system (e.g., phagocytosis) eliminate most of invading pathogens. There are a series of sequential events which play central role in specific reactions of lymphocytes to antigens. They are including antigen recognition, lymphocyte activation and expansion, antigen elimination, cellular contraction and memory formation. Once specific clones of naïve lymphocytes recognize a foreign antigen, they start to activate and proliferate to a large number of the cells that express identical receptors for the given antigen and thus belong to a clone (Burnet, 1959; Huppa and Davis, 2013). Expansion of specific lymphocyte clones with the same antigen specificity is also known as clonal expansion. Some of the progeny of these activated and expanded lymphocytes differentiate into effector cells. As effector lymphocytes have a limited lifetime and, once antigen is eliminated, most of the antigen-specific lymphocyte clones undergo apoptosis probably due to elimination of antigen as a survival signal, downregulation of anti-apoptotic proteins Bcl-2 and Bcl-XL and regulation of proapoptotic proteins Bax and Bim (McKinstry et al., 2010). However, a small number of antigen-specific lymphocyte clones continue to survive after antigen elimination (memory lymphocytes).

T lymphocytes and cell-mediated immunity

T lymphocytes, also called T cells, are essential components of the adaptive immune system. T cells derived from common lymphoid progenitors (CLPs) coming from the early sites of hematopoiesis (i.e., the bone marrow or fetal liver) are matured in the thymus and through expressing highly diverse antigen receptors on their surface they are capable to detect several foreign antigens. Large number of T cells expressing distinct antigen receptors- and therefore specificities- are generated during the development of thymocytes in the thymus (Kondo et al., 2019). In the secondary lymphoid tissues, conventional mature naïve T cells that express antigen-specific TCRs can be activated by their cognate peptide antigens displayed by major histocompatibility complex (MHC). Upon activation, T cells become effector cells and, in coordination with some components of innate immune system (phagocytic cells), they are able to produce anti-microbial cytokines and eliminate foreign antigens from sites of infections. The process of the activation of phagocytes and antigen-specific T cells, as well as the release of various cytokines in response to antigen is called cell-mediated immunity or cellular immunity.

T cell development and diversity

In the thymus, recently arrived progenitor T cells rapidly expand, differentiate and instructed under the effect of IL-7 and several other cell surface receptors (Hosokawa and Rothenberg, 2018). These events not only induce the expression of Notch-1 and other specific transcriptional regulators (e.g., GATA3) which drive progenitors to a T-cell lineage fate but also promote the expression of genes important in the TCR gene rearrangement. Subsequent differentiation of the T-cell lineage committed progenitors in the thymus includes an antigen-independent process in which a harmonized succession of DNA rearrangements results in the establishment of functional TCR genes encoding the γ and δ or α and β chains (Kumar et al., 2018).

The germline structure of the T cell receptor loci comprises of a sets of V (variable), D (diversity) and J (joining) gene segments. Rearrangements of V and J segments in the α and γ chains and V, D, and J segments in the β and δ chains leads to generation of functional and in-frame TCR genes. During a highly ordered procedure, a D segment is first randomly appended to a J segment, and subsequently a V segment is spliced to the preformed DJ complex (Fig. 1). This spatially and serially well-arranged process which is mediated by the V(D)J recombinase leads to combinatorial diversity in TCRs. Through binding to a recombinase signal sequence (RSS) flanking the borders of coding gene segments, V(D)J recombinase cleaves the DNA at these positions and, in consequence, generates hairpin structures on the coding segments. Next, Artemis endonuclease in complex with the DNA-dependent protein kinase (DNA-PK) creates single cuts adjacent to the tips of the hairpins leading to the formation of DNA termini. Further processing including random deletion and addition of nucleotides by a wide range of exonucleases and DNA polymerases is applied to the exposed 3' termini before ligation of the V and D segments and repairing of the DNA occur. The random cleavage of the hairpins by Artemis combined with incorporation of palindromic (P) nucleotides, addition of several non-templated (N)-nucleotides by terminal deoxyribonucleotidyl transferase (TdT) (which is recruited by the X-ray repair cross-complementing protein 4 (XRCC4)-like enzyme Cernunnos and DNA-PK) and exonucleolytic deletions altogether confer extreme variability in the antigen-binding pocket of the TCR which is also known as junctional diversity. Lastly, repair and ligation of the DNA breaks and the processed coding ends are done by DNA ligase IV and XRCC4 in a process called nonhomologous end-joining (NHEJ). Altogether, it is implicated that the defects in the genes involved in the V(D)J recombination (e.g., RAG, Artemis and DNA ligase IV) can lead to severe combined immunodeficiency disease (SCID).

During T cell development, sequential productive rearrangements of the two TCR chain genes (α and β or γ and δ) occurs in the developing thymocytes. These productive rearrangements give rise to generation of a full length TCR protein on the surface of thymocytes and drive the transition from the double-negative to the double-positive stage of thymocyte development. During this process, the TCR chains of the double positive T cells (expressing both CD4 and CD8 co-receptors) are complexed with various CD3 molecules to make a fully functional TCR complex. Double-positive T cells which are reside in the thymic cortex should undertake two selection processes (positive and negative selections) to mature into single-positive thymocytes (CD4⁺ or CD8⁺ T cells) which are found in the thymic medulla (Takaba and Takayanagi, 2017; Kondo et al., 2019). In the positive selection, if thymic double-positive T cells moderately bind to self-MHC molecules they will receive survival signals; otherwise they will die. Conversely, in the

Fig. 1 T cell receptor β (TCRβ) chain gene recombination. The successive recombination of a stochastic assortment of gene fragments determines TCR structure and specificity. During this highly ordered procedure and because of the endonuclease activity of the V (D)J recombinase, a D-J joining is first randomly occurs, and subsequently, a V segment is spliced to the preformed DJ complex leading to the formation of VDJ complex. Final spliced TCRβ mRNA can be translated into β chain protein.

negative selection, if double-positive T cells bind strongly to self-peptide/MHC antigens complexes they either will be deleted or differentiated into the natural regulatory T cells (Kitagawa and Sakaguchi, 2017). Moreover, further interaction of double-positive T cells with thymic epithelial MHC class I and class II molecules promotes their phenotype to CD8 single-positive and CD4 single-positive T cells respectively (Kurd and Robey, 2016; Gascoigne et al., 2016). Both CD4 and CD8 single-positive cells leave thymus and enter to the circulation as fully matured naive T cells (Fig. 2, lower panel). Expression and presentation of self-antigens (self-peptides), which are normally expressed in the distant organs, by thymic epithelial cells (TECs) is mediated by a transcription factor known as autoimmune regulator (AIRE) (Metzger and Anderson, 2011). AIRE plays a significant role in T cell selection and prevention of autoimmunity. Mutations in the AIRE gene can results in a rare autoimmune syndrome called autoimmune polyendocrinopathy syndrome type 1 (APS-1).

T cell activation

Recognition of peptide/MHC complex on an APC by TCR complex (i.e., TCR molecules plus their associated proteins such as CD3 and ζ) is the first step for the T cell activation. Due to rapid clustering of TCR complex, a stable physical interface also known as immunologic synapse is formed between the T cell and the APC (Colin-York et al., 2019). TCR complex specifically binds to the peptide/MHC complex through interaction between CD4/CD8 co-receptors (of T cells) and nonpolymorphic domains of MHC class I or MHC class II, respectively. Moreover, costimulatory signals delivered by receptors (such as CD28) along with TCR signals endorse activation of T cells representing two-signal hypothesis for T cell activation (Kaga et al., 1998). These events altogether facilitate the activation process by bringing the cytosolic domains of CD4/CD8 molecules which is associated with Src family protein tyrosine kinase Lck into proximity of the CD3 and ζ ITAMs (Salmond et al., 2009). Lck-mediated phosphorylation of ITAMs triggers the recruitment of a key signal transduction molecule Zeta-chain-associated protein kinase 70 Kd (ZAP-70) to CD3-associated ITAMs. Recruited ZAP-70 then phosphorylates a number of cytosolic proteins such as transmembrane protein linker of activated T cells (LAT) and SH2-containing leukocyte protein 76 Kd (SLP-76) molecules (Samelson, 2002). Phosphorylated LAT, in turn, serves as a docking site for some signaling molecules including SLP-76. These proteins also serve as docking sites for some signaling molecules and cellular enzymes such as PLCγ1 and exchange factors (e.g., SOS, so named because it is the mammalian homologue of a Drosophila protein called son of sevenless) that activate Ras and other small G proteins upstream of MAP kinases. These enzymes activate several cellular responses. For example, PLCγ1 catalyzes the hydrolysis of membrane inositol phospholipid phosphatidylinositol bisphosphate (PIP2), into inositol trisphosphate (IP3) and diacylglycerol (DAG). Through interaction with IP3 receptors on the endoplasmic reticulum, IP3 stimulates a rapid increase in cytosolic free calcium within minutes after T cell activation. This calcium flux, in turn, stimulates the influx of extracellular calcium (Vaeth et al., 2020; Chakraborty and Weiss, 2014; Hwang et al., 2020; Courtney et al., 2018).

Fig. 2 Stages of B cell and T cell development. Upper panel describes B cell development in the bone marrow in an antigen-independent manner. Later on, immature B cells leave the bone marrow and home to secondary lymph nodes to become mature. Upon exposure to invading pathogens, antigen-specific mature B cells can be activated and differentiated into antibody producing plasma cells. Lower panel represents T cell development in the thymus in an antigen-independent manner. During their development in the thymus, thymocytes undergo positive and negative selections in the thymic cortex and finally give rise to mature single positive $CD4^+$ or $CD8^+$ T cells. In the periphery, following exposure to antigen, mature naïve T cells can be activated and differentiated into different effector T cell subsets.

Cytosolic free calcium binds to a calcium-dependent regulatory protein calmodulin, which in turn activates several enzymes including the phosphatase calcineurin. The calcium-calmodulin pathway activates nuclear factor of activated T cells (NFAT) in the cytosol and facilitates translocation of dephosphorylated NFAT to the nucleus. At the same time, DAG, as the second breakdown product of PIP₂, activates the enzyme protein kinase C (PKC). The PKC- θ isoform which localizes to the immunologic synapse through intermediates activates transcription factor NF- κ B. Activation of the MAP kinase triggers another signaling cascade in the activated T cells. This signaling pathway is mediated by small guanine nucleotide-binding proteins (G proteins). Two most important members of this family activated downstream of the TCR are Ras and Rac. Each activates a different component or set of transcription factors (e.g., AP-1), and together they mediate many cellular responses of T cells (Fig. 3). The harmonized action of transcription factors regulate expression of various genes involved in differentiation, proliferation and effector function of T cells (Oh-Hora and Rao, 2008; Iborra et al., 2013; Monks et al., 1997; Weil and Israël, 2004; Heissmeyer et al., 2004).

Endogenous antigens (MHC class I-dependent pathway)

Mature $CD8^+$ T cells are activated on interaction of their TCRs with antigenic peptides (9–11 amino acids in length) complexed with MHC class I molecules. MHC class I molecules display peptides that are generally either derived from cytosolic protein antigens or the protein antigens phagocytosed and transported from vesicles into the cytosol—collectively called endogenous antigens. As MHC class I molecules present cytosolic peptides, the pathway of MHC class I presentation is generally called cytosolic or endogenous pathway. Upon their presence or expression in the cytosol, peptide antigens are subjected to the proteolytic degradation in the proteasomes. The peptides generated in proteasomes are then translocated by a dimeric protein called transporter associated with antigen processing (TAP) into the endoplasmic reticulum (ER), where empty class I MHC molecules are ready to capture the peptides. Empty class I MHC molecules, TAP and tapasin are a portion of a larger peptide-loading complex in the ER that also consists of calreticulin, calnexin and other parts that participate in the MHC class I assembly and loading. In the ER, ER-resident aminopeptidase (ERAP) also further trim peptides to the optimal size for MHC class I binding. The resultant stable peptide/MHC class I complexes are then transported to the cell surface. Once expressed on the cell surface, the peptide/class I complexes can be recognized by $CD8^+$ T cells (Blum et al., 2013; Mantegazza et al., 2013; Neefjes et al., 2011; Blees et al., 2017; Kotsias et al., 2019).

Fig. 3 Abbreviated schematic of the signaling pathways activated by the engagement of the T cell receptor (TCR). Following antigen recognition, TCR complex and co-receptors are clustered within membrane lipid rafts. This conformational alteration in TCR complex leads to activation of a series of signaling enzymes and adaptor proteins followed by activation of various intracellular signaling cascades such as MAP kinase signaling pathways and calcium- and PKC-mediated signaling pathways. These signaling pathways consequently activate transcription factors that bind to regulatory regions of many genes in T cells and thereby increase the transcription of genes involved in the proliferation, differentiation, and survival of T cells.

Exogenous antigens (MHC class II-dependent pathway)

Full functional activation of mature CD4⁺ T cells indeed depends on the interaction of TCR with antigenic peptides presented with MHC class II molecules. MHC class II molecules present peptides that are normally derived from extracellular protein antigens that are captured and internalized into endosomes by APCs. Internalized proteins are then subjected to degradation by proteases (such as cathepsins) that are active in acidic pH in the late endosomes and lysosomes to produce optimal size peptides (approximately 30 amino acids and more) that can bind to the peptide-binding clefts of MHC class II molecules. In simultaneous, newly synthesized MHC class II molecules in the ER are folded and transported to late endosomes and lysosomes with the aid of the invariant chain (Ii). Within the endosomal vesicles, the invariant chain is degraded by proteolytic enzymes (such as cathepsins) and converted to a 24-amino acid remnant called class II-associated invariant chain peptide (CLIP). Next, CLIP peptide is removed from peptide-binding cleft of MHC class II molecules by the action of HLA-DM molecule. The cleft is now accessible to antigenic peptides generated from exogenous antigenic peptides. Loading of exogenous antigenic peptides onto the MHC class II molecules leads to formation of stable peptide/MHC class II complexes. These complexes are next transported to the surface of the APC, where they are presented for recognition by CD4⁺ T cells (Blum et al., 2013; Mantegazza et al., 2013; Roche and Furuta, 2015; Neeffes et al., 2011; Kotsias et al., 2019; Unanue et al., 2016; Watts, 2012).

T cell subsets and their effector functions

The immune system responds in distinct and special ways to different antigens aiming to maximize its effectiveness. This distinct ways of response is obviously reflected in the generation of different subsets of T cells against various classes of the antigens. It is now clear T cell activation and differentiation are influenced by the type of APC and the cytokine milieu at the site of antigen encounter. The generated effector T cell subsets preserve the TCR specificity of their parent antigen-specific naïve T cells however express distinct transcription factors, cytokines and molecules that mediate their unique effector functions (Fig. 4; Kumar et al., 2018). In the following sections different subsets of T cells are described.

CD4⁺ T cell subsets

TCRαβ-bearing CD4⁺ T cells are the biggest class of T cells in the body. By production of cytokines and providing the cognate, these cells help the other immune cells such as B cells and mononuclear phagocytes to enhance their responses to the antigen and this is why these cells are also known as the T helper cells (TH cells).

T helper 1 (TH1) cells

Naïve CD4⁺ T cells differentiate into TH1 cells in a milieu containing IL-12 and IFN-γ (Macatonia et al., 1995). The primary source of IFN-γ may be nonspecific memory T cells or NK cells and the source of IL-12, during priming of naïve CD4⁺ T cells, is antigen-

Fig. 4 Differentiation of CD4⁺ T cells into different T cell subsets. Following antigen recognition and activation, naïve CD4⁺ T cells can differentiate into different T cells subsets depending on the type of APC and the cytokine milieu at the site of antigen encounter. The different subsets are characterized by expression of distinct transcription factors, cytokines and molecules that mediate their unique effector functions.

bearing dendritic cells. IFN- γ signals through STAT1 pathway and triggers the expression of T-bet, a master regulator of TH1 differentiation. IL-12 signals via activated Jak2 and Tyk2 and the STAT4 pathway, leading to extension of TH1 responses and augmentation of IFN- γ production by TH1 responder cells. Human TH1 cells can be distinguished by surface expression of CCR5 and CXCR3 (Zhu et al., 2009). TH1 cells play an important role in defense against intracellular bacteria, protozoa and fungi through production of a wide range of cytokines such as IFN- γ , TNF- α and IL-2. Supportive evidence has shown that deficiency in IFN- γ , T-bet, or IL-12 signaling results in a much higher susceptibility to intracellular infections (García et al., 2001). For example, patients with genetic defects in IL-12 and IFN- γ receptors or STAT1 signaling are more susceptible to intracellular infections such as Mycobacterium species. TH1 cells also augment cell-mediated immunity against the intracellular pathogenic protozoans such as Leishmania species (Moll and Röllighoff, 1990). In both above situations, TH1 cells produce IFN- γ that in turn augments the killing ability of these cells against intracellular bacteria and parasites. TH1 cell cytokines, in particular IFN- γ , also activate NK cells and cytolytic T cells for killing of intracellular microbes and virally infected targets.

T helper 2 (TH2) cells

Naïve CD4⁺ T cells differentiate into TH2 cells in a milieu containing IL-4. The primary source of IL-4 may be basophils and mast cells which are in the proximity of T cell priming. IL-4 signals through the STAT6 pathway and promotes expression of GATA3, a master regulator of Th2 differentiation that drives IL-4 expression and downregulates the expression of IFN- γ . Human TH2 cells are differentiated by surface expression of CRTH2, CCR3 and CCR4 (Zhu et al., 2009; Walker and McKenzie, 2018). TH2 cell-driven inflammatory response involves eosinophils and basophils, mast cells and IgE-class switched B cells as effector cells. This response is also characterized by mast cell activation and degranulation due to cross-linking surface-bound IgE. Through production of IL-4, IL-5, and IL-13, Th2 cells coordinate B cell class switching to IgE, thereby priming basophils and mast cells for granule release, augmenting chemotaxis of eosinophils and basophils, and enhancing mucus production, respectively. These events play critical roles in the promotion of type 2 immune responses which are important for hypersensitivity immune responses and expulsion of extracellular parasites (e.g., helminth infections) and bacterial infection (Gurram and Zhu, 2019). Lastly, although a balanced TH2 cell-mediated immune response is critical for elimination of extracellular parasites; imbalanced Th2 response can cause some pathologic circumstances such as allergy and airway hypersensitivity (Nakayama et al., 2017).

T helper 17 (TH17) cells

TH17 cells are the third subset of CD4⁺ T helper (TH) cells. In cytokine milieu of IL-6 and TGF- β , naïve CD4⁺ T cells are developed into TH17 cells. TH17 cells are characterized by production of IL-17, TNF- α , and IL-22 as well as expression of the transcription

factor ROR γ t (Zhu et al., 2009; Ciofani et al., 2012). Unlike TH1 and TH2 cells, TH17 cells have distinctive properties which make these cells well suited for the host protection against some extracellular bacteria and fungi. The pattern of cytokines produced by TH17 cells seem to be critical for the immunity against extracellular bacteria and fungi owing to their role in the recruitment, activation and migration of neutrophils, promoting the expression of tight-junction proteins (e.g., claudins) as well as stimulating the production of antimicrobial peptides (e.g., defensins) (Ouyang et al., 2008). While TH17 cells play a critical role in host defense against extracellular bacteria and fungi, they have been implicated in the immunopathogenesis of a number of T autoimmune diseases such as rheumatoid arthritis (RA) and psoriasis (Stockinger and Omenetti, 2017). TH17 cells also have a key role in chronic allergic inflammatory responses of some inflammatory diseases such as asthma. In human, TH17 deficiency, for example due to mutations in the transcription factor STAT3, can cause the hyper-IgE syndrome (or Job's syndrome) which is associated with recurrent infections and decreased T cell-mediated inflammatory response (Holland et al., 2007).

T helper 9 (TH9) cells

TH9 cells have been most recently described as a subset of CD4⁺ T helper cells. These cells are characterized by the expression of CD4 and CCR6 and the lack of CCR4 as well as production of the IL-9, IL-10 and IL-21. IL-4 and TGF- β signaling drive differentiation of naïve CD4⁺ T cells into TH9 differentiation (Zhu et al., 2009). TGF- β signaling in TH9 cells activates transcription factor Smad and induces the expression of transcription factor PU.1. In TH9 cells, PU.1 directly binds to the *Il9* promoter and recruits chromatin-modifying enzymes which amplify *Il9*-gene transcription (Kaplan et al., 2015). Similar to TH2 cells, TH9 cells are thought to mediate helminthic immunity through production of IL-9. This cytokine induces expansion and recruitment of mast cells. TH9-derived IL-21 can also promote TH17 differentiation, B-cell survival, antibody class switching, NK cell proliferation and activation. Experimental animal models also propose that TH9 cells may play a role in the pathogenesis of atopic and autoimmune diseases (Clark and Schlapbach, 2017).

T helper 22 (TH22)

TH22 cells have been identified as a distinct CD4⁺ T cell subset within the past decade. IL-6 and IL-1 signaling but not TGF- β is required for differentiation of naïve CD4⁺ T cells into TH22 cells. These cells are characterized by the expression of CD4, CCR6, and skin-homing receptors CCR4 and CCR10, as well as production of IL-22, IL-13 and TNF- α . The production of IL-22 in these cells is thought to depend on the expression and activation of aryl hydrocarbon receptor (AhR). The role of TH22 cells in immune responses is still being elucidated, but they seem to not only stimulate wound healing and tissue remodeling but also regulate innate defense mechanisms (e.g., antibacterial protein production) and promote barrier function at mucosal sites. The impact of TH22 cells and IL-22 expression has been assessed in various chronic inflammatory diseases. IL-22 signaling has been shown to have protective roles in experimental models of inflammatory diseases such inflammatory bowel disease (IBD) and asthma through stimulation of various homeostatic mechanisms in the epithelial barriers (Eyerich et al., 2009; Pennino et al., 2013). In contrast, excessive production of IL-22 by skin-resident TH22 cells has been appeared to be an important driver of inflammation in cutaneous inflammatory diseases, such as psoriasis (Ho and Kupper, 2019).

T follicular helper (Tfh) cells

Tfh cells are a distinct activated CD4⁺ T cell subset which resides in B cell zones of lymph nodes and the spleen due to the expression of the CXCR5 (Moser, 2015). IL-6, IL-2, ICOS and TCR signaling altogether induce the differentiation of newly activated CD4⁺ T cells into Tfh cells during priming of dendritic cells through regulation of Bcl6 and CXCR5 (Zhu et al., 2009). Expression of Bcl6 (often referred to as the Tfh master regulator transcription factor) is induced through IL6/IL-6R signaling. This transcription factor not only regulates Tfh cell differentiation but also induces expression of CXCR5 and formation of germinal center. Tfh cells are recognized an indispensable T CD4⁺ cell subset in triggering the formation and maintenance of germinal center immune responses and generation of immunological memory through expression of CD40L, IL-21 and IL-4. Dysregulation of Tfh-mediated immune responses have the potential to trigger the formation of overactivated germinal centers characterized by the presence of aberrantly mutated B cell clones. These aberrantly mutated B cells can become autoreactive and thereby promote antibody-mediated autoimmune diseases. Higher level of Tfh-like cells has been found in the blood of some patients with Sjögren syndrome. However, it remains to be fully elucidated in humans (Crotty, 2014; Vinuesa et al., 2016).

Regulatory T cells (Tregs)

Regulatory T cells (Tregs) are a subset of CD4⁺ T cells characterized by the expression of the transcription factor Foxp3, CD4, and CD25. There are two main types of Tregs: naturally occurring thymus-derived Foxp3⁺CD127^{lo}CD4⁺ Tregs (nTregs) and in vivo-induced Foxp3⁺CD4⁺ T (iTregs) (Zhu et al., 2009). iTregs arise from naïve Foxp3⁻CD4⁺ T cells in the periphery. In the thymus, double positive (CD4⁺ CD8⁺) thymocytes through recognizing self-antigens with high avidity may differentiate into nTregs. Upon stimulation and in the presence of cytokines such as TGF- β and IL-2, naïve CD4⁺ Foxp3⁻ T cells can differentiate into CD4⁺ Foxp3⁺ iTregs (Kitagawa and Sakaguchi, 2017). Tregs balance the immune system by preventing or dampening of immunological responsiveness and maintaining of immunological tolerance in the steady state and under pathophysiological conditions (Sakaguchi et al., 2020). They perform their immunosuppressive functions through different mechanisms such as inhibitory cytokine production, metabolic disruption, cytotoxicity, cell to cell contact, modulation of dendritic cells and competitive uptake of IL-2 (Vignali et al., 2008). Considering the regulatory function of Tregs, defects either in the abundance and/or function of Tregs can disturb immune system responses and immunological tolerance. For example, mutations in Foxp3 gene leads to immune

dysregulation, polyendocrinopathy, enteropathy, and X-linked inheritance (IPEX) syndrome in humans resulting in lethal autoimmunity. IL-10 producing Tregs (Tr1 cells) are another subset of CD4⁺Tregs that do not express Foxp3. In presence of IL-27 and TGF- β , Tr1-like cells are generated. These cells are characterized by CD4⁺ CD49b⁺ LAG-3⁺ CD226⁺ cells. Similar to non-Tr1 cells, activated Tr1 cells exert their immunosuppressive function through various above-mentioned mechanisms (Roncarolo et al., 2018).

CD8⁺ T cell subsets

TCR $\alpha\beta$ -bearing CD8⁺ T cells represent one of the main classes of T cells. CD8⁺ T cells primarily recognize peptides presented by MHC Class I molecules. CD8⁺ effector T cells [also called cytolytic T lymphocytes (CTLs)] can kill the cells harboring intracellular pathogens and transformed cells by three main mechanisms. (i) Secretion of cytokines with anti-tumoral and anti-viral effects; (ii) Production of cytotoxic granules; (iii) Destruction of infected and malignant cells via Fas/FasL interactions (Zhang and Bevan, 2011).

CD8⁺ CTLs are not as diverse as of CD4⁺ TH cells; however, they can differentiate into two different subsets named TC1 and TC2. TC1 and TC2 cells are loosely similar to TH1 and TH2 cells in terms of the cytokines that stimulate their development as well as cytokines they produce. TC1 cells produce IFN- γ , but no IL-4. In the IL-4-enriched milieu, CTLs differentiate into TC2 cells, which produce much more IL-4 and IL-5 than IFN- γ . Although both CTL subsets are potent in the killing of host target cells, TC1 cells perform both perforin and Fas-mediated mechanisms, while TC2 cells only use perforin (Vukmanovic-Stejic et al., 2000; Paul and Ohashi, 2020).

Other T cell subsets

Besides CD8⁺ and CD4⁺ T cells, there are smaller subsets of T cells that represent distinct properties and likely perform particular functions in host immune defense. The best characterized of these subsets are NKT cells and $\gamma\delta$ T cells. Both NKT cells and $\gamma\delta$ T cells are often proposed to be at the intersection of adaptive and innate immunity.

$\gamma\delta$ T cells

$\gamma\delta$ T cells are a small subset of T cells which are mostly populated in the epithelium of tissues. $\gamma\delta$ T cell abundance is largely varied in different tissues and species, however less than 5% of all T cells generally express TCR $\gamma\delta$. Although the TCR is created by DNA rearrangement, unlike conventional TCR $\alpha\beta$, the actual diversity of TCR $\gamma\delta$ repertoire is limited because only a small number of the V, D, and J segments are used in mature $\gamma\delta$ T cells (Pellicci et al., 2020). This limited diversity indicate that $\gamma\delta$ T cells may have evolved to recognize a small group of microbial antigens and serve as an early defense against a small number of frequently encountered pathogens at epithelial linings (Chien et al., 2014). In developing double negative (CD4⁻CD8⁻) thymocytes, rearrangement of TCR loci of β , γ , or δ is plausible. If a cell can make productive rearrangements in γ and δ loci before it makes a productive TCR β rearrangement, the cells will committed to $\gamma\delta$ T cell lineage. Although antigens that activate $\gamma\delta$ T cells are not well-identified, it has been shown that lipid antigens and heat-shock proteins can activate these cells. It has been found that $\gamma\delta$ T cells are not restricted to antigen presentation by MHC molecules and do not require antigen processing (Scanlon, 2019). Some $\gamma\delta$ T cells recognize antigens via nonclassical MHC molecules, whereas others seem to recognize whole antigens without antigen processing. $\gamma\delta$ T cells can recognize target molecules on stressed, infected and/or transformed cells and secrete cytotoxic molecules, inflammatory cytokines and stimulate adaptive immunity. They can also lyse target cells by antibody-dependent cellular cytotoxicity (ADCC). Through secretion of IFN- γ and IL-17, $\gamma\delta$ T cells augment the expression of MHC class I, and thereby positively induce CTL-mediated immune response. $\gamma\delta$ T cells also can interact with DCs and develop Th1 response. Recent investigations have revealed that human V γ 9/V δ 2 T cells are also able to do phagocytosis, a function that was thought to be exclusive to innate immune cells (Lawand et al., 2017).

Natural killer T (NKT) cells

Natural killer T (NKT) cells are a specialized subset of T cells that share morphological and functional characteristics of both NK cells and T cells. Many of NKT cells recognize lipid and glycolipid antigens through interaction with a nonpolymorphic MHC class I molecule-also known as CD1d. NKT cells make up about 0.1% of peripheral blood T cells. NKT cells are recognized by a restricted TCR repertoire and this is why these cells are also called invariant NKT (iNKT) cells (Pellicci et al., 2020). Based on the different features such as reactivity to α -GalCer and CD1-dependent antigen recognition, NK T cells are classified into three subsets (Table 2) (Dhodapkar and Kumar, 2017; Godfrey et al., 2004).

NKT cells are capable to rapidly respond to antigen (without prior activation) and produce cytokines such as IL-4 and IFN- γ . NKT cell-derived cytokines and chemokines can modulate recruitment, activation and immune response of many innate and adaptive immune cells (Krovi and Gapin, 2018). The role of NKT cells in protective immunity or disease in humans is not fully defined. However, recent studies have revealed that deficiency or dysfunction of NKT cells can result in the development of some autoimmune diseases such as diabetes (Griseri et al., 2005). Intriguingly, NKT cells have been reported to exacerbate certain other diseases such as human asthma (Iwamura and Nakayama, 2018).

B cells and antibody-mediated immunity

B cells, also known as B lymphocytes, make up the humoral immunity arm of the adaptive immune system. This type of immunity is largely mediated by antibodies produced by antigen-specific B cells (and plasma cells), so it is often called antibody-mediated

Table 2 Comparative features of NKT cell subsets.

Feature	Type I cells (Classical NKT cells)	Type I cells (non-classical NKT cells)	NKT like cells
Developmental requirements	IL-15	Not established	Not established
CD1d dependency	Yes	Yes	No (MHC I & II)
Reactivity to α -GalCer	Yes	No	No (various lipids and peptides)
TCR α -chain	V α 14-J α 18 (mice) V α 24-J α 18 (humans)	Diverse	Diverse
NK1.1 expression	+ (Resting mature) -/Low (immature or post-activation)	$\pm$	+
IL-4 production	Yes	Yes	Yes
IFN- γ production	Yes	Yes	Yes
Tissue location	Liver and spleen, intestine and pulmonary mucosa	Liver and spleen	Liver, spleen and bone marrow

immunity. Humoral immunity is the major defense barrier against extracellular pathogens and microbial toxins as antibodies can neutralize or flag (opsonize) microbes and their toxins and contributes to their elimination (Cohn and Langman, 1990). Antibody-mediated elimination of microbes is facilitated by various effector mechanisms such as antibody-dependent cellular cytotoxicity (ADCC), antibody-dependent cellular phagocytosis (ADCP), antibody-mediated complement activation and antibody (i.e., IgA)-mediated immune exclusion (Lu et al., 2018).

B cell development and diversity

Before birth, B cells arise from committed precursors in the fetal liver and after birth they are developed in the bone marrow. In the bone marrow, under influence of signals received from several cell surface receptors, common lymphoid progenitors (CLPs) are not only induced to express B-cell specific transcriptional regulators (e.g., PU.1, IKAROS, EBF, E2A, IRF8 and Pax-5) that drive cell fate decision to a B-cell lineage but also promote the expression of genes important in the B-cell receptor (BCR) gene rearrangement (Busslinger, 2004; Hardy and Hayakawa, 2001; Zehentmeier and Pereira, 2019; Fistonich et al., 2018; Nagasawa, 2006). During the development of B cells and in a spatially and sequentially ordered events, developing B cells in the absence of exogenous antigen undertake DNA rearrangement, express Immunoglobulin (Ig) genes, undertake selection and proliferation at the pre-antigen receptor checkpoint and finally immature B cells acquire antigen specificity and give rise to mature naïve B cells in the spleen to shape conventional naïve B cell repertoire (Fig. 2, upper panel) (Melchers, 2015). The genes encoding antibodies are rearranged and assembled from gene segments in a way completely resemble to the process for TCR genes. During their maturation in bone marrow, B cell-committed progenitors undertake distinct steps, each featured by diverse cell surface markers and a unique pattern of Ig gene expression. As the earliest bone marrow cell committed to the B cell lineage, pro-B cells express surface markers such as CD19 and CD10. V(D)J recombinase is expressed at this stage and the first gene recombination event arises at the Ig heavy chain locus (IgH). During recombination of IgH locus, D to J joining is randomly occurs and subsequently a V segment is spliced to the DJ complex, giving rise to a rearranged VDJ exon. The rearranged Ig heavy chain gene and C μ region exons are altogether transcribed to produce a primary transcript. The primary transcript is then subjected to RNA processing in which the introns are removed and exons (VDJ and C μ exon) appended together, giving rise to a spliced mRNA for the μ heavy chain (Fig. 5). If the mRNA was in-frame and productive, rearranged μ heavy chain mRNA is translated, leading to synthesis of the μ protein. Only pro-B cells that undergo in-frame and productive DNA rearrangements continue to survive and differentiate into pre-B cells. Pre-B cells are developing B cells that express the μ heavy chain, surrogate light chains (i.e., the λ 5 and V pre-B proteins), and signal-transducing proteins (i.e., Ig α and Ig β) on the cell surface, that altogether make a complex known as the pre-B cell receptor. Following antigen-independent assembly of pre-BCR, a kinase called Bruton's tyrosine kinase (Btk) is activated. This enzyme is required for signal transduction of Pre-BCR and has a prominent role in the proliferation, maturation and survival of pre-B cells. In humans, mutations in the BTK gene leads to a rare genetic disorder called X-linked agammaglobulinemia (XLA), which is characterized by the absence of mature B cells (Satterthwaite and Witte, 2000). The pre-BCR signaling also regulates the allelic exclusion phenomenon. Based on this phenomenon, only an individual B cell clone with monospecificity is generated (Winkler and Mårtensson, 2018; Sonoda et al., 1997). As pre-B cell mature, the pre-BCR signaling also stimulates κ light chain gene rearrangement and inactivates the expression of surrogate light chain gene. DNA recombination in the κ light chain locus happens in a similar way as in the Ig heavy chain locus. However, unlike Ig heavy chain loci, there are no D segments in the light chain loci, and thus recombination involves only the V-J joining. If the developing B cell can productively rearrange, it will produce a κ light chain protein which assembles with the previously produced μ chain to generate a complete IgM molecule. Otherwise, the developing B cell undergoes a λ light chain gene rearrangement and again generates a complete IgM molecule. The λ light chain gene rearrangement arises only if the κ rearrangement was not productive. This phenomenon is called light chain isotype exclusion. Developing B cells that express complete IgM are called immature B cells. Cell membrane IgM in association with signaling molecules Ig α and Ig β makes a BCR complex. Upon encounter with multivalent antigens in the bone marrow, immature B cells that recognize antigen with high avidity do not proliferate and differentiate rather they may undergo receptor editing or clonal deletion. Non-self-reactive immature B cells can finally leave the bone marrow and enter to the spleen to complete their maturation. After maturation, mature B cells (IgM⁺ IgD⁺)

Fig. 5 Ig heavy chain gene recombination and expression. Serial recombination of a random assortment of gene fragments defines heavy chain structure and specificity. During recombination of IgH locus, D to J joining is casual and consequently a V segment is spliced to the DJ complex to create a rearranged VDJ exon. The rearranged Ig heavy chain gene and C μ region exons are altogether transcribed to produce a primary transcript. In the next step, through RNA processing, the introns of the primary transcript are removed and VDJ exon is joined to C μ exon, giving rise to a spliced mRNA for the μ heavy chain.

can migrate to other secondary lymphoid organs. Similar to TCR, combinatorial and junctional diversities hugely contribute to the variability and binding specificity of BCR (Imkeller and Wardemann, 2018).

B cell activation

Membrane IgM and IgD are the antigen recognition receptors expressed by mature naive B cells. In association with two signaling molecules Ig α (CD79a) and Ig β (CD79b), IgM and IgD make B cell receptor (BCR) complex. The class of antibodies IgM and IgD can be switched in different differentiation stages of B cells. For example, in class-switched B cells and memory B cells antigen-recognition domain of BCR complex can be made of the IgE, IgG or IgA classes. In this complex, Ig α and Ig β transduce antigen-recognition-derived signals through their ITAM motifs located in their cytoplasmic tails. BCR cross-linking with multivalent antigen initiates BCR signaling through recruitment and activation of Src family kinases such as Lyn and Fyn which are loosely associated with cell membrane (Shen et al., 2019). Activation of these kinases results in the phosphorylation of the tyrosine residues on the ITAMs of Ig α and Ig β . These phosphorylated ITAMs serve as a docking site for the Syk tyrosine kinase. ITAM-associated Syk is then autophosphorylated and activated and leading to phosphorylation of critical adaptor proteins such as SH2-binding leukocyte phosphoprotein of 65 kD (SLP-65), also called BLNK, or B cell linker protein (Cheng et al., 1995; Pappu et al., 1999). Phosphorylated SLP-65 facilitates the recruitment of guanine nucleotide exchange proteins that can distinctly activate Ras and Rac, PLC γ 2, and PKC- β , each commonly involving in the activation of different signaling pathways and transcription factors such as Fos (downstream of Ras and ERK activation), JunB (downstream of Rac and JNK activation), and NF- κ B (downstream of Btk, PLC γ 2, and PKC- β activation). All of these signaling pathways and their associated molecules are involved in stimulating proliferation, differentiation and survival of B cells (Fig. 6) (Yam-Puc et al., 2018; Schroeder et al., 2019).

In addition to activation of BCR signaling, attenuation of BCR signaling is also required to limit uncontrolled humoral immunity and lymphoproliferation. This is mainly mediated by the action of Fc γ RIIB and CD22/Siglec-2 that serve as a terminator/attenuator of B cell activation. The cytoplasmic tail of CD22 and Fc γ RIIB contain an ITIM. Phosphorylation of tyrosine residues of ITIM serves as a docking site for the SHIP (for Fc γ RIIB) and SHP-1 (for CD22). The recruited SHIP and SHP-1 remove phosphates from the several adaptor proteins and enzymes involved in B cell receptor signaling and hence terminate B cell activation (Nitschke, 2005; Clark and Giltiay, 2018).

T-independent antigens

Some antigens stimulate antibody production without T cell involvement. These antigens are called thymus (or T)-independent (TI) antigens. TI antigens generally do not induce isotype switching and immunological memory which are hallmarks of T cell-dependent antigens. TI antigens are subdivided into two groups based on their ability to activate B cells: T-independent type I antigens and T-independent type II antigens. Most TI type I antigens are molecules (e.g., LPS and endotoxin) that can directly, without considering antigen specificity, induce B cell mitosis and polyclonal antibody production (mainly IgM) (Ulevitch and

Fig. 6 Abbreviated schematic of the signaling pathways activated by engagement of the B cell receptor (BCR). Following antigen recognition, BCR signaling through recruitment and activation of a wide spectrum of enzymes and adaptor proteins is initiated. Activation of these molecules leads to activation of different signaling pathways and transcription factors such as Fos (downstream of Ras and ERK activation), JunB (downstream of Rac and JNK activation), and NF-κB (downstream of Btk, PLCγ2, and PKC-β activation). All of these signaling pathways and their downstream transcription factors are involved in the induction of proliferation, differentiation and survival of B cells.

Tobias, 1995). Such antigens have the ability to activate B cell in the absence of T cell help probably through the crosslinking of putative LPS receptors (e.g., TLR-4). T-independent antigens types II are typically repeating polymers such as polysaccharides (e.g., dextran, ficoll,), glycolipids, and nucleic acids. They can interact with multiple BCRs on the cell surface and extensively cross-link them, and as a result, trigger signal transduction in B cells (Mond et al., 1995). This activating signal transduction with the additional cues provided by cytokines (e.g., IL-2, IL-3 and IFN-γ) or other cell [e.g., signals induced by transmembrane activator and CamL interactor (TACI) ligands such as a proliferation-inducing ligand (APRIL) and B cell-activating factor (BAFF)] provided by dendritic cells can not only altogether induce differentiation of activated B cells into memory B cells or plasma cells but also can promote Ig isotype switching in the absence of T cell help (Bortnick et al., 2010; Defrance et al., 2011). It seems that T-independent humoral immunity in harmony with the innate immunity ensure a rapid initial response to invading pathogens before the recruitment of effective cognate T cell help aiming to restrict the spreading and pathogenicity of microbes at early phases of infection.

T-dependent antigens

Thymus(T)-dependent antigens are typically soluble protein antigens that required to be internalized by specific B cells, processed, and presented to MHC class II-restricted helper T cells, which then activate the B cells for antibody production (Adler et al., 2017). As these proteins antigens only can induce an antibody response with the help of T helper cells, they are classified as T-dependent antigens. To initiate an antibody-mediated immune response, a T-dependent antigen should be primarily delivered to a secondary lymphoid tissue either via dendritic cells and phagocytic cells or the draining lymphatics. In both scenarios, the antigen is processed by the APCs and is presented via MHC class II molecules to antigen-specific CD4⁺ T cells, resulting in the differentiation and

activation of antigen-specific T cells. At the same time, B cells which are populated in the cortex of primary follicles in the lymph nodes can recognize their specific antigen. After initial interaction of B cells and cognate T cells in the B-T border, activated B cells can experience two scenarios. In the first scenario, activated B cells can instantly become short-lived plasma cells characterized by secretion of low-affinity antibody without somatic mutation. In the second scenario, activated B cells accompanied with CXCR5-expressing TH cells move deeper into the B cell zone and form germinal centers (GCs) (Kerfoot et al., 2011). The specialized type of TH cell that facilitate the formation of germinal centers is called Tfh cell. Through GC interactions and in harmony with follicular dendritic cells (FDCs), Tfh cells by production of cytokines (e.g., IL-21) and expression of interacting surface molecules (e.g., CD40L) provide essential signals for Ig class switching somatic hypermutation and affinity maturation, B cell proliferation and differentiation into antibody-producing plasma cells and long-lived memory B cells (Wan et al., 2019). Defects in these events may lead to some immunodeficiencies such as hyper-IgM syndrome.

B cell subsets and their effector functions

B cells are generally described as the cells that can produce antibodies, function as secondary APCs and generate many immunoregulatory cytokines. There are different subsets of B cells that are distinct in terms of phenotype, anatomical locations and functional features. The main B cell subsets are follicular B cells, marginal zone B cells, B-1 cells and regulatory B cells (Bregs). In the following sections, the effector of function of these cells is discussed.

Follicular (FO) B cells

FO B cells are essential for T-dependent humoral immunity. This type of immunity is initiated by crosslinking of highly diverse, clonally distributed sets of antigen-specific BCRs on FO B cells and completed by help of cognate T cells specific for the same antigen. This cognate interaction results in the secretion of a high-affinity and class switched antibodies. During a T-dependent B cell response, if the activated FO B cells get through GC reactions and experience CD40 signaling, they upregulate Bcl6 and hence undergo Ig isotype switching, somatic hypermutation and affinity maturation and finally differentiate into long-lived plasma cells. If the activated FO B cells do not get through the GC reactions and do not receive sustained CD40 signaling, they do not upregulate Bcl6 and hence do not undergo isotype switching or somatic hypermutation and instantly differentiate into short-lived plasma cells (de Maio et al., 2020; Weinstein et al., 2016). Unlike long-lived plasma cells, these cells are populated in the secondary lymphoid tissues and peripheral sites. Short-lived plasma secrete low-affinity IgM antibody for a short period of time (2–3 days) and then the cells are subjected to cell death.

Marginal zone (MZ) B cells

MZ B cells are a distinct subset of B cells characterized by expression of high levels of IgM, CD21, CD1 and CD9 with dim to slight expression levels of IgD, CD23, CD5 and CD11b. MZ B cells respond readily to TI antigens. They play a key role in the very early phases of the splenic humoral immunity against blood-borne antigens (Martin and Kearney, 2002). MZ B cell-mediated antibody responses are initiated in the marginal zone of spleen. MZ macrophages concentrated around the lymphoid follicles in the spleen are mostly effective at catching the blood-borne microbial antigens. These antigens may last for long period of time on the surface of MZ macrophages, where they can be detected by antigen-specific MZ B cells. After activation with antigen (usually a TI antigen), MZ B cells cannot upregulate Bcl6 and hence these cells instantly proliferate and differentiate into short-lived IgM-secreting plasma cells without undertaking somatic hypermutation and isotype switching. It is postulated that MZ-derived IgM-secreting plasma cells contribute to the generation of natural antibodies (Maddur et al., 2020). These antibodies are found in the circulation of normal human subjects and are seemed to be produced in the absence of exposure to the pathogens. Natural antibodies are essentially low affinity antibodies mainly with IgM isotype. By recognition of carbohydrates and oxidized lipids which are found on the bacterial membrane and on apoptotic cells, natural antibodies not only provide a rapid adaptive humoral immunity against blood-borne bacterial infections but also improve the phagocytosis of apoptotic cells (Zouali and Richard, 2011; Cerutti et al., 2013). Interestingly, MZ B cells can act as regulatory cells in autoimmune context through the induction of tolerance by apoptotic cells (Marinkovic and Marinkovic, 2020).

B-1 B cells

B-1 B cells represent another lineage of B cells primarily arisen from the fetal liver-derived stem cells and most of them undergo self-renewal in the periphery (Montecino-Rodriguez and Dorshkind, 2012). During B cell ontogeny, B-1 B cells develop earlier than FO B cells; express an oligoclonal repertoire of variable genes with minimal BCR diversity. Many B-1 B cells express the CD5 (Ly-1) molecule. Through secretion of broadly cross-reactive natural antibodies such as IgM (mainly), IgA and IgG3, these cells respond to TI antigens primarily in the peritoneal and pleural cavities as well as in mucosal tissues (Smith and Baumgarth, 2019). Peritoneal B-1 B cells are seemed to be the primary source of natural antibodies. These antibodies are thought to be stimulated by bacteria that settled down in the gastrointestinal tract. In addition to their capability to produce natural antibodies, B-1 cells are able to produce cytokines (e.g., IL-3 and GM-CSF) as well as uptake and present antigens to T cells during pathogen invasion. B-1 cells can be additionally subdivided into B-1a (CD19, B220, IgM, CD43 and CD5⁺ B-1 cells) and B-1b (CD19, B220, IgM, CD43 and CD5⁻ B-1 cells) subsets. In contrast to B-1a cells, the B-1b subset can be arisen from precursors in the adult bone marrow. Recent functional studies also point out that B-1a B cells are the main source of natural IgM antibody while B-1b cells seem to be the major source of TI antibody production and long-lasting protective immunity against bacterial infections (Baumgarth, 2017; Haas et al., 2005).

Regulatory B cells (Bregs)

Similar to Tregs, the regulatory B cells (Bregs) are now generally recognized as a significant regulatory element of the immune system that suppresses immunological inflammation. However, unlike Treg cells, currently there are no distinctive phenotypic or lineage markers as well as specific cytokine profiles that truly characterize Bregs. Hence, the term Bregs refers to B cells that possess immunoregulatory functions. In this regard, virtually all B cell subset can differentiate into Bregs in the presence of appropriate stimuli such as TLR ligands and anti-CD40 (Rosser and Mauri, 2015). Nevertheless, various subsets of Breg with different phenotypes have been defined. For instance, human blood Bregs are CD19⁺CD24hiCD27⁺, MZ Bregs are characterized by CD19⁺CD21⁺CD1d⁺CD5⁺CD23^{low} and B-1 cell-derived Bregs are defined as CD19⁺CD5⁺IgMhiCD23⁻CD21⁻CD11b⁺ (Iwata et al., 2011; Bankoti et al., 2012; Shimomura et al., 2008). All Bregs can also differentiate into plasmablasts and conventional plasma cells. It seems that Immunoregulatory function of Bregs is mediated through different mechanisms such as secretion of immunosuppressive cytokines, cell-cell contact immunosuppression, secretion of anti-inflammatory antibodies (e.g., IgA and IgG4) and enhancing the production of Tregs (Rosser and Mauri, 2015).

Immunological memory

Immunological memory is a quite unique feature of the adaptive immune system as it can store information of antigen upon first exposure and can elicit a quicker and stronger secondary immune response to the same antigen upon re-exposure probably due to presence of long-lived memory T cells and B cells generated during primary immune response. Immunological memory is not only a key protection mechanism against invading of a wide range of microbes, but also it plays significant role in vaccine development and the success of vaccination (Farber et al., 2016).

Memory T cells

Until recently, it was hard to phenotypically distinguish memory T cells from naïve and effector T cells. Most of memory T cells are in the quiescent state, however unlike naïve T cells, they do not need stringent requirements for their activation. For instance, naïve T cells are almost exclusively activated by DCs, while memory T cells can be activated by various types of APC such as DCs, B cells and macrophages probably due to the expression of different surface adhesion molecules and costimulatory receptors that make memory T cells more receptive for interaction with various types of APC. Due to difference in epigenetic configuration, memory T cells also respond more quickly to antigen re-exposure compared to naïve T cells (Chen et al., 2018). Lastly, recirculation pattern of memory T cells is different with those of naïve or effector T cells (Mueller et al., 2013; Lefrançois, 2006). Memory cells may arise from effector cells based on a linear pathway model, or from naïve T cells that upon antigen stimulation divergently differentiate into effector and memory cells (divergent pathway model) (Moulton and Farber, 2006). It is now unclear how an antigen-activated T cell can differentiate into long-lived memory cells or short-lived effector T cells. Although the signals that drive these two fates are not fully elucidated, it seems that types of transcription factors that are induced during T cell priming determine the T cell fate. For example, T-bet promote naïve T cell differentiation into TH1 cells, whereas Blimp-1 induces the generation of memory T cells. Furthermore, it is not clear whether the expression of these transcription factors is stochastic event or is a response to some specific external cues. Following antigen elimination, activated T cells undergo cellular contraction. During this phase 90–95% of T cells are subjected to apoptosis, however remaining 5–10% of T cells are differentiated into memory T cells. Memory T cells are generally subdivided into four different memory cells including stem memory T cells (Tscm), effector memory T cells (Tem), central memory T cells (Tcm) and tissue-resident memory T cells (Trm). Table 4 summarizes features of various subsets of memory T cell (Rahimi and Luster, 2020; Mueller et al., 2013; Sathaliyawala et al., 2013). Table 3 summarizes features of various subsets of memory T cell.

Memory B cells

Humoral memory participates in the host defense at least at two levels: the primary level is contributed to the presence of pre-existing protective antibodies produced by long-lived plasma cells. This level of humoral memory is considered as constitutive humoral memory. If the primary level was overwhelmed, the second level of humoral memory that is rapid reactivation of microbe-

Table 3 Memory T cell subsets.

Subset	Phenotype	Effector function	Proliferation potential	Trafficking	Function
Tscm	CD44 [±] , CD62L ⁺ , CCR7 ⁺ , CD127 ⁺ , CD69 ⁻ , CD103 ⁻	+	++	Lymph node-homing and with lesser extend in the spleen and bone marrow	Reconstitutes the entire spectrum of memory and effector T cells subsets
Tcm	CD44 ^{high} , CD62L ⁺ , CCR7 ⁺ , CD127 ⁺ , CD69 ⁻ , CD103 ⁻	+	±	Lymph node-homing and circulatory	Confers more powerful immunity against pathogens
Tem	CD44 ^{high} , CD62L ⁻ , CCR7 ⁻ , CD127 ⁺ , CD69 ⁻ , CD103 ⁻	+	-	Tissue homing and circulatory	Mainly responsible for cytotoxic action against pathogens
Trm	CD44 ^{high} , CD62L ⁻ , CCR7 ⁻ , CD11a ^{high} , CD69 ⁺ , CD103 ⁺	+	+	Tissue homing and non-circulatory	Rapid response to pathogens that breach epithelium linings and any relevant pathogen present

Table 4 Human memory B cell subsets.

Subset	Origin	Location/trafficking	Function
D19 ⁺ CD27 ⁺ IgM ⁺ IgD ⁺ (similar to circulating marginal zone B cells)	Early GC, GC independent	Second lymphoid tissues (MZ of spleen), blood	Ti response TD response?
CD19 ⁺ CD27 ⁺ IgM ⁺ IgD ⁺ (IgM-ONLY)	Early GC	Second lymphoid tissues, blood	TD response?
Class-switched CD19 ⁺ CD27 ⁺ IgM ⁺ (IgG ⁺ or IgA ⁺)	Late GC	Mucosal tissues, blood	TD response

experienced memory B cells becomes functional. This level of humoral memory is called reactive humoral memory (Inoue et al., 2018). Although humoral memory is mediated in part by pre-existing protective antibodies produced by long-lived plasma cells, these cells are usually not considered as memory B cells. Instead, long-lived and quiescent B cells that quickly respond to antigen rechallenge are considered as memory B cells. Following T cell-dependent B cell responses in the border of B-T cell zone, activated B cells proliferate and may follow one of the three fates: differentiation into extrafollicular short-lived plasma cells, germinal center-independent memory B cells or move into the follicle to form a GC (Palm and Henry, 2019). Various studies have pointed out that there should be a master regulator of memory B cell differentiation similar to IRF4/Blimp-1/XBP-1 for plasma cells. Although expression of Bach2 in the light-zone germinal center B cells has been supposed to act as a differentiation regulator of germinal center B cells to memory B cells, a memory B cell-specific transcription factor is yet to be discovered (Kometani et al., 2013). Table 4 summarizes features of various human memory B cells.

Concluding remarks

Although innate immunity as the first line of defense is still critical for the protection against many invading microbes, the evolution of microbes that learnt to evade innate immunity through employing a wide spectrum of strategies leads to counter-evolution of more effective adaptive immunity. The adaptive immunity possesses some unique characteristics such as clonal diversity and specificity as well as immunological memory that make it distinct from innate immunity. These characteristics altogether confer adaptive immunity the abilities to vastly increase the opportunities to more specifically recognize and further memorize its experiences of exposures with different pathogens. Since lymphocyte repertoire is shaped in the absence of antigen, it can hugely maximize the risk of unsuitable attack against self-antigens. Hence it is required that adaptive immune responses are finely regulated by several regulatory mechanisms (e.g., regulatory cells) to blunt such self-poisoning attack.

Cell-mediated immune responses, known as cellular immunity, involves recognition of foreign antigens by naïve CD4⁺ or CD8⁺ T cells, their activation, and finally differentiation to effector or memory T cells. As one of the two main arms of adaptive immune responses, cellular immunity contributes to a wide range of defense mechanisms against a variety of pathogens.

T cells not only play a basic role in cell-mediated immunity, but they also have a fundamental role in promoting humoral immune responses.

T lymphocyte development in the thymus

T cells develop from progenitor cells that migrate from bone marrow to the thymus, where they undergo maturation and selection processes and acquire different specificities. Each clone of naïve T lymphocyte expresses a unique TCR when leaves the thymus. Additionally, depending on the type of major histocompatibility complex (MHC, e.g., class I or II) that the developing T lymphocyte encounters as it passes through the thymus, either CD8⁺ or CD4⁺ T cell develops and egresses from the thymus (Kurd and Robey, 2016; Spits, 2002).

Peripheral T cell pool comprises of naïve T cells, memory T cells and also, regulatory T cells. Naïve T cells are the ones that leave the thymus while express TCR and CD4 (or CD8) on their surface and have not exposed to any kind of antigen, yet (Van Den Broek et al., 2018). Naïve T cells circulate throughout secondary lymphoid tissues via high endothelial venules. After specific recognition of an antigen by naïve T cells, they become activated and converted to the effector T cells with diverse functional capacities. These effector T cells migrate preferentially to the peripheral sites of infections. Also, some activated T cells can convert to memory T cells. Memory T cells equipped for early and robust immune responses against subsequent encounters to the same antigen (Masopust and Schenkel, 2013; Sallusto et al., 1999). The third population of T cell pool is regulatory T cells. The majority of regulatory T cells develop in the thymus; however, some of them are differentiated in peripheral tissues (Sakaguchi et al., 2010). Naïve, effector, and memory T cells can be distinguished based on their functions, the receptors they express on their surface, and their preferred homing sites.

T cell aging

Since the thymus undergoes involution following puberty, T cells seem to be age-sensitive. In young individuals, the majority of T cell pool is composed of newly generated naïve T cells which have left the thymus recently. The contribution of the thymus for the generation of naïve T cells declines progressively after puberty. Accordingly, maintenance of naïve T cells after puberty relies on homeostatic proliferation of naïve T cells (Goronzy and Weyand, 2017; Sauce et al., 2012; Surh and Sprent, 2008).

Production of thymus-derived regulatory T cells decrease with age advancement. The peripheral blood regulatory T cells involve both naïve- like and memory-like regulatory T cells even in CD4⁺ or CD8⁺ T cells. However, following the aging decline of naïve- like

regulatory T cells is more prominent compared to memory-like regulatory T cells. By contrast, the memory-like population of T cells is increasing with the aging (Goronzy and Weyand, 2017).

Memory T cell homeostasis is more dynamic compared to naïve T cell; however, response patterns of memory T cells differ according to the type of pathogen (e.g., viruses) that each individual has encounters with. For example, cytomegalovirus (CMV) specific memory cells are dominant in elderly individuals while this is not the case with varicella-zoster virus (VZV); as many elderly have experienced shingles. Although the frequency of memory T cells are upraised with age advancement, inconsistent findings of memory T cells against distinct pathogens, such as the memory T cells against VZV and CMV in the elderly, may be related to the viral load or latency state in these viral infections (Goronzy and Weyand, 2017).

T cell receptor (TCR) and recognition of antigens

Unlike B lymphocytes, T lymphocytes generally recognize peptides in association with MHC molecules, emphasizing the recognition of proteins by T lymphocytes. Also, CD4⁺ T cells could help B lymphocyte to produce antibodies against proteins. Each clone of T lymphocyte expresses a specific T cell receptor (TCR) which identifies a peptide in combination with an MHC molecule (Davis et al., 1998).

TCR is composed of two different transmembrane chains. The majority of T lymphocytes express α and β chains as the TCR; however, a small number of T cells express $\gamma\delta$ TCRs. It is noteworthy that TCR is presented as a complex on the surface of T cells and other molecules such as CD3 and ζ homodimers accompany the TCR. In addition to the TCR complex, each T cell express one of these two co-receptors, CD4 or CD8 (Li and Mariuzza, 2013; Pennock et al., 2013; Smith-Garvin et al., 2009). CD4⁺ T cells are known as helper T cells (Th), while CD8⁺ T cells are called cytotoxic T cells (CTL or Tc) (Geginat et al., 2014; Wan, 2010).

Steps of T cell activation (general features)

Activation of T cells needs a kind of antigen-presenting cell (APC). Naïve T cells could be activated by the most potent APCs, known as dendritic cells (DCs); while effector or memory T cells could be activated by any type of APC, including DCs, Macrophages or B lymphocytes (Croft, 1994). Naïve T cells are generally activated in secondary lymphoid tissues; while effector or memory T cells could be activated at peripheral sites of inflammation in addition to lymphoid tissues (Gasteiger et al., 2016).

T cell activation is maintained through a proper interaction between an APC and a T cell, known as an immunologic synapse. Three signals are needed for the activation of T lymphocytes. The first signal is provided by a peptide, embedded in the cleft of an MHC molecule. This signal is obligatory for the initiation of T cell activation; however, in the case of most T cells, it is not sufficient. The second signal is supplied by costimulatory molecules. These molecules are expressed on the surface of APCs and as the name implies, they stimulate T cells in combination with signals provided by peptide antigens. The third signal is achieved by cytokines which are secreted from the APCs following their interaction with T lymphocytes. These cytokines lead to the differentiation of T cells that are more appropriate for responding to a pathogen that has entered the body (Corthay, 2006).

T cell costimulation

A wide range of costimulatory molecules was identified; most of them belong to B7-family. The most known B7 costimulatory molecules are B7-1 (CD80) and B7-2 (CD86), which are expressed on the surface of professional APCs. These molecules could bind to CD28 which is expressed constitutively on the surface of T lymphocytes. This pathway provides the second signal for initiation of the activation of T cells, particularly naïve T lymphocytes. Expression of B7-1 and B7-2 on the APCs follows a sequential pattern. In this way, B7-2 is detected earlier and augmented upon T cell activation, while B7-1 appears at a later time on the surface of APCs. This sequential pattern could indicate that B7-2 is more important in the initiation of T cell activation; however, B7-1 seems to play a significant role in the maintenance of T cell activation. This means that B7-1 and B7-2 could not replace each other in terms of their functions (Esensten et al., 2016).

CD28 is the most prominent costimulatory receptor on the surface of T lymphocytes, which could ligate with both B7-1 and B7-2 on the surface of APCs. It belongs to the immunoglobulin (Ig) superfamily. The majority of CD4⁺ (80%) and approximately 50% of CD8⁺ T cells express CD28 on their surface (Attanasio and Wherry, 2016; Esensten et al., 2016).

Another member of costimulatory receptors that have demonstrated stimulatory function is inducible-costimulator (ICOS, CD278). ICOS is not expressed constitutively on resting T cells; however, its expression on activated T cells suggests that both TCR and CD28 signals could have a role in ICOS expression on the surface of activated T cells. Nevertheless, it has been demonstrated that ICOS expression is not entirely dependent on CD28, especially in CD8⁺ T lymphocytes. Also, CD28 and ICOS have not shown redundant roles. ICOS binds to ICOS ligand (ICOSL, CD275) instead of B7-1 or B7-2. ICOSL is expressed on the surface of APCs, including dendritic cells, macrophages, and B lymphocytes. Apart from the essential role of the ICOS/ICOSL in humoral immunity, this interaction plays a principal role in T cell proliferation and activation (Dong et al., 2001; Wikenheiser and Stumhofer, 2016). Although IL-2 production increases following the interaction of ICOS and ICOSL, this production seems to be less prominent compared to the engagement of CD28 and B7. Contrary, the production of IL-10 is more eminent in the reaction of ICOS with its ligand. The involvement of ICOS could induce both Th1 and Th2 responses; albeit, Th2 responses are more dependent on ICOS

engagement. Similarly, in CD8⁺ T cells, ICOS interaction with ICOSL could upraise the amount of IL-2 and IFN- γ production by cytotoxic T cells and enhance their activation. It has shown that this interaction could not affect the cytolytic activity of these cells (Carreno and Collins, 2002; Wikenheiser and Stumhofer, 2016).

OX40 (CD134) is a member of the tumor necrosis factor receptor (TNFR) superfamily and represents a marker of T cell activation. This molecule can act as a costimulatory receptor and is appeared on the surface of activated CD4⁺ or CD8⁺ T lymphocytes. OX40 ligand (OX40L, CD252) is not constitutively expressed; however, it could be induced on the surface of APCs in addition to many other immune and non-immune cells. OX40 signaling could enhance T cell survival and proliferation upon their activation and also, augment clonal expansion of effector or memory T cells. OX40 could inhibit the suppressive function of natural regulatory T cells (nTreg) and also, antagonize the generation of inducible regulatory T cells (iTreg) (Croft et al., 2009).

CD40 ligand (CD154) is a member of the TNF superfamily. It is expressed on T lymphocytes upon their activation. It attaches to CD40 which belongs to the TNFR superfamily and is expressed on the surface of different APCs. This interaction can enhance the expression of costimulatory molecules on the surface of APCs as well as the production of cytokines by these cells. Also, CD40-CD40L interactivity could promote the potential of APCs to present antigens. Accordingly, the ability of APCs to activate T cells will improve. This process is named; licensing, which indicates licensing of APCs for the more effective triggering of T lymphocytes (Elgueta et al., 2009). Moreover, this interaction could promote the responses that are related to the production of immunoglobulins in germinal centers such as isotype switching, production of antibodies with higher affinity and also, production of long-lived plasma cells (Chand Dakal et al., 2020; Elgueta et al., 2009).

T cell co-inhibition

Cytotoxic T-lymphocyte-associated protein 4 (CTLA4) or CD152 belongs to the immunoglobulin superfamily. Although approximately 30% identity has been shown in sequences of CTLA4 and CD28, and also similar ligands on the surface of APCs, CTLA4 delivers inhibitory signals to T cells compared to stimulatory signals provided by CD28. CTLA-4 is not expressed on the surface of naïve T cells; however, it is expressed on the surface of regulatory T cells, and its expression increases upon activation on the surface of conventional T cells. CTLA4 is fundamentally an intracellular antigen which transferred to the surface of T lymphocyte upon activation. Also, its expression on the cell membrane is transient due to rapid internalization (Carreno and Collins, 2002; Chambers et al., 2001). CTLA4 remains for a longer duration on the surface of memory and regulatory T lymphocytes (Jago et al., 2004).

CTLA4 represents a co-inhibitory receptor for B7 molecules. CTLA4 inhibits T cell activation through different mechanisms. Some of these mechanisms are related to the effect of CTLA4 on the function of the same T cell that has primarily expressed CTLA4; these mechanisms are known as cell-intrinsic mechanisms. Four mechanisms were categorized as cell-intrinsic mechanisms; First of all, CTLA4 can interfere with signaling pathways of CD3 and CD28. Secondly, compared to CD28, CTLA4 displays a higher affinity for B7-1 and B7-2, resulted in the competition of CTLA4 with CD28 and therefore, suppression of efficient T cell responses. Thirdly, CTLA4 strengthens the adhesion of T cells to the APCs and shortens the duration of their interaction. Finally, splice variants of CTLA4 may attach to B7-1 or B7-2 and prevents T cell activation. On the other side, CTLA4 could affect the expression of costimulatory molecules on the encountered APCs. These mechanisms are categorized as cell-extrinsic mechanisms. Three different extrinsic mechanisms have been explained up to now. First of all, CTLA4 can induce the production of Indolamine 2, 3-dioxygenase (IDO) within APCs, which in turn deprives T lymphocytes of tryptophan and inhibits their activation. The second cell-extrinsic mechanism includes downregulation of costimulatory molecules (B7-1/B7-2) on the surface of APCs and, the third cell-extrinsic mechanism involves reducing the accessibility of B7-1 and B7-2 through triggering the endocytosis of these molecules (Schildberg et al., 2016).

Programmed cell death protein 1 (PD1, CD279) has the potential to appear on the surface of T lymphocytes following their activation. PD1 belongs to the Ig superfamily, and it could attach to two ligands, including programmed death-ligand 1 (PD-L1, CD274) and PD-L2 (CD273). PD-L1 and PD-L2, members of the B7 family, are expressed on the surface of a wide range of immune and non-immune cells. After T cell activation, the interaction of PD1 (on the T cell membrane) with either PD-L1 or PD-L2 (on the surface of APC) can lead to the cell cycle arrest of T cell, reducing the production of IL-2 and finally, attenuation of immune responses. This downregulation plays a fundamental role in returning the immune responses to the baseline state and establishment of a homeostasis condition in the final stages of T cell responses (Carreno and Collins, 2002).

CD4⁺ T cell activation results

Clonal expansion

Following the recognition of peptide antigens in combination with costimulatory signals, T lymphocytes undergo proliferation. T cell proliferation is dependent on the production of interleukin 2 (IL-2) by activated T cells and also the appearance of a complete form of the IL-2 receptor, which is composed of α chain (CD25) in addition to β (CD122) and γ (CD132) chains, on their surface. This stage is called clonal expansion and provides sufficient numbers of a specific clone of T lymphocytes. IL-2 receptor is not expressed in complete form on the surface of naïve T cells; however, it promptly appears on the surface of T cells upon their activation. This time-dependent expression pattern guarantees the proliferation of specific clones of T lymphocytes during adaptive T cell responses (Pekalski et al., 2013).

Th1, Th2, Th17 differentiation

The second stage in T cell responses involves the differentiation of expanded T cells to effector T lymphocytes. Both CD4⁺ and CD8⁺ T cells will undergo differentiation to produce more efficient T cells that could combat more effectually against the pathogen that the human body has encountered. Differentiation of T cells to effector T cells takes place in secondary lymphoid tissues. According to cytokine milieu during the activation process, CD4⁺ T cells could differentiate to a variety of helper T (Th) cells (Zhu et al., 2010). Each of these Th subsets displays a distinctive transcription factor and produces a unique set of cytokines which represents its properties for the eradication of a particular type of invader microorganism. However, plasticity has been shown in CD4⁺ T cells. In a certain microenvironment, upregulated expression of other transcription factors could happen which leads to the differentiation of a distinct subset of T cells. Furthermore, micro RNAs and long non-coding RNAs demonstrate a peculiar role in promoting differentiation of different T cell populations (Sallusto, 2016).

Structurally, T cells categorize to CD4⁺ T cells, known as helper T cells or Th cells; and CD8⁺ T cells as cytotoxic T cells (CTL or Tc). In addition to the distinct expression of these coreceptors on the surface of these subsets, their function is also completely different. Helper T cells could assist other cell populations, such as macrophages or B lymphocytes, for more activation and hence, properly eradication of the pathogens; however, the CTLs are responsible for killing the viral infected or stressed tumor cells. Either of these effector functions can be achieved after the activation of naïve T cells and their further differentiation (Wan, 2010; Zhang and Bevan, 2011).

T helper 1 (Th1) cells

Th1 cells have an essential role in defense against intracellular microorganisms including, viruses, intracellular bacteria, and some intracellular parasites. However, the expression of chemokine receptors is different on the surface of various Th1 cells that defend against these diverse pathogens (Sallusto, 2016).

Th1 cells differentiate in microenvironments that are rich in interleukin-12 (IL-12) (Scott, 1993). Although other cytokines such as IL-18 and interferons type 1 (IFN- α , - β) could promote the differentiation of Th1 cells, IL-12 plays a dominant role in this process (Nakanishi, 2018; Nakanishi et al., 2001; Ramos et al., 2007). Another cytokine with the ability to promote the differentiation of Th1 cells is IFN- γ . IFN- γ , in combination with TCR signaling, can induce the first wave of T-bet expression, which is IL-12 independent. Afterward, IL-12 signaling will initiate that can trigger the second wave of T-bet expression and supports further Th1 differentiation (Lazarevic et al., 2013). The primary sources of IL-12 are DCs and macrophages which phagocytose the microorganism and become activated upon it (Trinchieri et al., 2003). Similarly, IL-18 produced by the same APCs provides synergistic effects with IL-12 (Nakanishi, 2018; Stoll et al., 1998). On the other hand, innate immune responses usually produce IFNs. IFN- α , and IFN- β are produced by virally infected cells, while natural killer cells release IFN- γ (Billiau and Matthys, 2009; Schoenborn and Wilson, 2007).

The chief cytokine that is produced by Th1 cells is interferon γ (IFN- γ). This cytokine can affect dendritic cells and macrophages that had previously driven the differentiation of Th1 cells. Reciprocally, IL-12 signaling in Th cells results in inducing the expression of T-bet; in its turn, T-bet promotes the transcription of IFN- γ (Usui et al., 2006).

One of the consequences related to the activation of CD4⁺ T cells and their subsequent differentiation to Th1 cells is the activation of macrophages. This response is typically known as cell-mediated immunity (CMI) and represents the principal cell-mediated immune response against the pathogens which have been up-taken, processed, and presented as peptides on the surface of macrophages. Activated Th1 cells produce IFN- γ which impress on cognate macrophages and enhance their ability for digestion and presentation of pathogen's antigens. Reciprocally, macrophages will produce IL-12 which could augment the potency of Th1 cells (Trinchieri, 2003). Proper instances of CMI are the infection with intracellular *Mycobacterium tuberculosis* and tuberculoid leprosy (Dannenberg, 1989; Turk, 1969).

T helper 2 (Th2) cells

T helper 2 cells are known to have a significant role in humoral immunity and defense against helminth infections. Besides, Th2 cells play a principal role in a group of prevalent diseases that are allergies. Th2 cells differentiate in the presence of IL-4 that promotes the phosphorylation of STAT6 and also the induction of GATA3. In addition to IL-4, other cytokines such as thymic stromal lymphopoietin (TSLP), IL-25, and IL-33 play fundamental roles in inducing the Th2 cells. GATA3 is the main transcription factor of Th2 cells that promotes the differentiation of Th2 cells while inhibits Th1 differentiation. Also, GATA3 demonstrates a regulatory role in Th2 proliferation. GATA3 seems to be essential for continuous chromatin remodeling of Th2 cytokine gene loci. Although epigenetic modifications induce and maintain GATA3, the expression of all Th2 related cytokines is not under the control of GATA3 (Nakayama et al., 2017; Sasaki et al., 2013).

IL-4, IL-5, IL-13, and IL-9 are the chief cytokines that are produced by Th2 cells, and their expression is under the control of GATA3. Th2 cytokines have a profound effect in defense against intestinal worms. After lodgment of helminths in the intestine, innate immune and non-immune cells recognize derived pathogen-associated molecular patterns (PAMPs). Epithelial cells release cytokines such as IL-33, TSLP, and IL-25 upon activation. These cytokines can influence the other innate immune cells such as DCs, group 2 innate lymphoid cells (ILC2) and, basophils. ILC2 cells will produce IL-13, and this cytokine could modulate dendritic cells in such a way that promotes Th2 differentiation. The cytokines produced by Th2 cells have the potency to reinforce the Th2 responses. Th2 cells could promote the mechanisms that lead to the extrusion of worms from the intestine. IL-13 increases the turnover of intestinal epithelial cells and induces the helminths excretion. Indeed both IL-13 and IL-4 can induce goblet cell

hyperplasia as well as mucus secretion and contractility of intestine muscles, all of them aid in the excretion of the parasite. IL-5 could recruit eosinophils to the intestine, while IL-9 could attract mast cells. Both eosinophils and mast cells demonstrate crucial roles in immune responses against helminths (Cortés et al., 2017; Wynn, 2015).

Another mechanism that is responsible for defense against helminths mediates by the interaction of Th2 cells, B lymphocytes, and eosinophils. Th2 or T follicular helper (Tfh) derived cytokines could promote isotype switching to Immunoglobulin E (IgE) in activated B lymphocytes. Produced IgE covers the worm and facilitates the recognition of opsonized worm by Fc receptors on the surface of eosinophils. This recognition activates the eosinophils which finally, leads to the release of eosinophil granule contents on the surface of worms and the induction of helminth degradation (Huang and Appleton, 2016).

Contrary to Th1 cells that activate M1 macrophages to produce IL-12 and establishment of cell-mediated immune responses, Th2 cells activate M2 macrophages. These macrophages produce anti-inflammatory cytokines and also demonstrate a prominent role in tissue repair by inducing the production of growth factors and angiogenic cytokines. Also, Th2 cells play a fundamental role in the pathogenesis of type 1 hypersensitivity reactions, including allergic reactions (Van Dyken and Locksley, 2013).

T helper 17 (Th17) cells

Th17 cells comprise a distinct subset of CD4⁺ T cells that produce interleukin 17 (IL-17) A, IL-17F, IL-21, and IL-22. Transforming growth factor β (TGF- β) in combination with IL-6 could promote the differentiation of naïve CD4⁺ T cells to Th17 cells. Also, IL-21 and IL-23 could mediate the amplification of Th17 cells. These Th17 cells express ROR- γ t as their main transcription factor. Nevertheless, in human, the combination of IL-1, IL-6, and IL-23 has been reported to be able to induce a category of Th17 cells which are different from the aforementioned Th17 cells, as they express both ROR- γ t and T-bet simultaneously and exhibit more potent pathogenic roles (Patel and Kuchroo, 2015).

Th17 cells are involved in various extracellular bacterial and fungal infections. They recruit neutrophils to the site of infection and induce inflammation. Also, they provide barrier immunity by inducing the production of antimicrobial peptides and maintaining the integrity of epithelial cells. Pathogenic Th17 cells have a role in several autoimmune diseases such as psoriasis, inflammatory bowel disease, and multiple sclerosis (Hou and Bishu, 2020; Li et al., 2020; Moser et al., 2020).

T Follicular helper cells (Tfh)

T follicular helper cells are a distinct population of T cells that are predominantly located in the germinal centers of secondary lymphoid tissues, including lymph nodes and spleen. Their function is to help B lymphocytes for antibody production. Contrary to other effector CD4⁺ (e.g., Th1, Th2, Th17) or CD8⁺ cytotoxic T lymphocytes, they could not act as effector T cells in peripheral sites of infections. It was shown that two kinds of APCs, including DCs and B lymphocytes, are necessary for the differentiation of Tfh cells. Bcl6 represents the essential transcription factor for the differentiation of Tfh cells. Also, it has been shown that the repression of Blimp1 is required for Tfh differentiation. Although Tfh cells have the potential to express transcription factors that are related to other Th subsets, Bcl6 suppresses this expression in Tfh cells which are located in germinal centers. Tfh cells migrate to germinal centers and provide CD40L, IL-21, and IL-4 there. Tfh cells indicate a profound effect in inducing the production of plasma cells and long-lived memory B cells that can produce high-affinity antibodies (Crotty, 2019).

Regulatory T cells (Treg)

Regulatory T cells are a distinct population of T cells with a prominent role in the suppression of aberrant immune responses and induction of self-tolerance. CD4⁺ CD25⁺ T cells express FoxP3 as their main transcription factor and they could be generated in the thymus or induced at the sites of inflammation in peripheral tissues. The former are known as natural regulatory T cells (nTreg) and the latter is recognized as induced regulatory T cells (iTreg). Although FoxP3 is known as the main transcription factor which is related to Treg cells, it has been demonstrated that the expression of FoxP3 is not singly sufficient for acquiring the properties of Treg cells. Epigenetic changes can be responsible for the occurrence of some modifications in Treg cells. Although epigenetic changes can be reversed; however in some loci of Treg cells, these modifications are preserved (Ohkura et al., 2013).

Treg cells can suppress the immune responses in a specific or non-specific manner. Specific suppression is the consequence of direct contact between TCR and MHC, on the surface of a Treg and a dendritic cell, respectively. This interaction can induce a tolerogenic DC that is not able to stimulate T cell responses via several mechanisms. Engagement of B7 with CTLA4 prevents the reaction of B7-1 or 2 with CD28 on the surface of naïve or effector T cells. This event leads to the unresponsiveness of T lymphocytes to autoantigens. Moreover, this interaction could remove peptide-MHC complexes from the cell membrane of DC that impedes the presentation of that particular peptide. Also, the involvement of CTLA4 with B7 can lead to the production of indolamine 2, 3-dioxygenase (IDO) that deprives T cells of tryptophan and inhibits their proliferation.

Treg cells can establish non-specific suppression via a variety of mechanisms. One probable mechanism is the degradation of ATP to adenosine by CD39/CD73 that are existed on the surface of Treg cells. Increased adenosine could suppress the ability of DCs to present antigens. The second mechanism includes the production of IL-10 and TGF- β by Treg cells that repress the activation of T cells (Shevryev and Tereshchenko, 2020; Zhao et al., 2017).

Accordingly, Treg cells could provide tolerance to self-antigens in the thymus and self or non-self-antigens in peripheral tissues. Impairment in the function of Treg cells could lead to a wide range of auto-immune disorders (Zhao et al., 2017).

CD8⁺ T cell activation results

CD8⁺ T cells are developed in the thymus and leave it while they express T cell receptors (TCRs) on their surface. They recognize peptide antigens that are in association with MHC class I molecules on the surface of infected cells. After this recognition, CD8⁺ T cells undergo proliferation, activation, and finally, differentiation to effector or memory T cells. Effector CD8⁺ T cells are known as cytotoxic T lymphocytes (CTLs), acquiring the capacity of killing the infected target cells with viruses or intracytosolic bacteria. Besides, CTLs can lyse tumor cells.

CD8⁺ T cell requires three signals for being activated. These signals include specific antigen recognition, costimulation, and the presence of cytokines in the microenvironment. Activation of naïve CD8⁺ T cells initiates in secondary lymphoid tissues. Infected cells do not express costimulatory molecules. Therefore, the presence of dendritic cells is necessary to provide costimulation for the activation of naïve CD8⁺ T cells. Dendritic cells, as the most potent APCs, can uptake the infected cells or their associated antigens. After the antigen is processed, it is presented by MHCI molecules on the surface of DCs. Concurrently, DCs provide costimulatory signals for CD8⁺ T cells. These two signals induce the activation of CD8⁺ T cells. This process is called cross-presentation and seems to be necessary for the initiation of the activation of naïve CD8⁺ T cells. However, the potential of cross-presentation is diverse amongst different subsets of DCs (Joffre et al., 2012).

Following activation and differentiation of CD8⁺ T cells to CTLs, they acquire the characteristics which are necessary for killing the infected target cells. Transcription factors, such as T-bet and eomesodermin, are specified in CTLs. These transcription factors can induce the expression of granzyme and perforin, as the contents of CTL granules, and also, IFN- γ as the main cytokine of CTLs. Effector CD8⁺ T cells release the content of their granules on the surface of infected target cells upon activation. Perforin creates pores on the surface of target cells, and granzyme penetrates through these pores into infected target cells. Granzyme can activate caspases and induce apoptosis of infected cells (Voskoboinik et al., 2015). Besides this mechanism, CTLs can induce apoptosis of target infected or tumor cells by the interaction of Fas and Fas-ligand (Malyshkina et al., 2017; Rode et al., 2004).

In some cases, the activation of CD8⁺ T cells requires receiving the help of CD4⁺ T cells. In general, the presence of CD4⁺ T cells appears to be necessary for CTL activation when weak innate immune responses evoked. One of the mechanisms of this help is provided by inducing more potent APCs throughout CD40- CD40L interaction (Schoenberger et al., 1998). The other mechanism involves the secretion of cytokines through helper T cells which in turn can affect the CD8⁺ T cells and activate them (Wang and Livingstone, 2003; Wilson and Livingstone, 2008).

CD8⁺ T cell exhaustion

During chronic viral infections and cancers, persistent T cell stimulation causes CD8⁺ T cell exhaustion. The exhausted CD8⁺ T cells exhibit some characteristics, including; loss of effector functions, persistently expression of inhibitory receptors, altered metabolic state, and some emerging epigenetic alterations. Persistent exposure to antigen induces the upregulation of co-inhibitory receptors in T cells. Also, it can increase the expression of their cognate ligands in virally infected or tumor cells. Indeed, in this context, the production of type 1 interferons by infected cells or TGF- β by tumor cells is increased that causes more exhaustion in CD8⁺ T cells (McLane et al., 2019).

Memory T cells

After T cell activation, a population of memory T cells is developed. Activation of CD4⁺ or CD8⁺ T cells can induce memory cells. Compared to naïve T cells, memory T cells have a longer lifespan and respond more quickly after antigen exposure. These are equipped cells that can make more intensely immune responses after activation.

The number of memory T cells gradually increases after each exposure to the antigen which provides more memory T cells with age. On the other hand, memory T cells undergo self-proliferation in the absence of antigen which is maintained by IL7 or IL-15 for CD4⁺ or CD8⁺ T cells, respectively (Surh and Sprent, 2008).

From the functional viewpoint, CD4⁺ or CD8⁺ memory cells are classified as central or effector memory cells. Central memory T cells (TCM) migrate predominantly to the lymph nodes; however, effector memory T cells (TEM) settle more in peripheral sites of infection. These homing characteristics are related to the expression of distinct receptors on the surface of these two subsets of memory T cells. Central memory T cells express CCR7 and CD62L, which cause this population to migrate to the lymph nodes. TCMs can proliferate and supply a higher number of effector cells after exposure to antigen, while TEMs provide more potent effector functions, such as the production of cytokine or cytotoxic activities, after stimulation with antigen. Effector memory T cells do not express CCR7 and CD62L (Sallusto et al., 2004).

A population of memory T cells resides in non-lymphoid tissues such as skin and mucosal surfaces. This population is named tissue-resident memory cells that can defend rapidly against further challenges with the antigen in different tissues. The expression of transcription factors by this population seems to be different and depends on their location (Topham and Reilly, 2018).

For rapid response to pathogens entering a peripheral tissue, tissue-resident memory T cells, as well as effector memory T cells that migrate immediately to the site of infection, play a key role. If these responses fail to control the pathogen, an in-situ response will occur. This in situ response may involve in-situ proliferation and retention of resident or migratory effector memory cells. However, central memory T cell proliferation initiates in draining lymph nodes to provide a sufficient number of memory T cells for later stages. In the next step, the progeny of these central memory T cells migrate to the site of infection to fight the pathogen and control the pathogen completely (Masopust and Schenkel, 2013).

$\gamma\delta$ T cells

A minority of human T cells are $\gamma\delta$ T cells. These T cells express a TCR that is composed of γ and δ chains. Contrary to conventional T cells, $\gamma\delta$ T cells demonstrate lower diversity in their TCRs. Accordingly, the range of their ligands is more limited. There is a limited repertoire of V gene segments in $\gamma\delta$ T cells for rearrangement compared to those that are available in the T cells that express $\alpha\beta$ TCRs. A group of $\gamma\delta$ T cells involves $\delta 1^+$ $\gamma\delta$ T cells that where locate preferentially in the intestines. This population of $\gamma\delta$ T cells can recognize lipids in combination with CD1d and also some stress-induced ligands. They are responsible for defense against pathogens that enter the body through mucosal surfaces. V $\gamma 9$ V $\delta 2$ T cells represent another group of $\gamma\delta$ T cells. This population includes approximately 10% of blood T cells; however, they can locate in other tissues such as the intestine. Ligands of this subset of $\gamma\delta$ T cells are phospho-antigens. $\gamma\delta$ T cells can recognize stress-induced molecules by some other receptors such as NKG2D. Also, transformed cells could express high levels of these stress-induced molecules that can engage NKG2D. Engagement of NKG2D in addition to TCR could cause effector functions of $\gamma\delta$ T cells, including proliferation, T cell activation, and cytokine production (Adams et al., 2015; Poggi and Zocchi, 2014).

Introduction

T lymphocytes are a major component of the adaptive immune response and the immune system as a whole. T cells express a T cell receptor (TCR) assembled through V(D)J recombination, similar to the B cell receptor. The TCR is a heterodimer composed of an α chain and a β chain. Unlike B cells, conventional T cells recognize antigen in the form of short peptide sequences associated with major histocompatibility complex (MHC) molecules on the surface of antigen presenting cells (APCs). T cells can be broadly characterized based on the expression of either CD4 or CD8 coreceptors. In addition to $\alpha\beta$ T cells, there is a number of unconventional T cells that differ in the expression of key markers and/or function. Unlike the majority of leukocytes that develop in the bone marrow, T cell development occurs in the thymus. The thymus provides a unique environment that facilitates the development of T cells, while inhibiting other lymphoid lineages. Understanding the factors involved in T cell development is critical for both basic immunology research and biomedical applications. Errors in T cell development have been shown to give rise to cancer, autoimmune disorders and immunodeficiencies, and understanding T lymphopoiesis can provide potential insights for new treatments. This chapter serves to present fundamental concepts pertaining to the development of T cells, with a specific focus on the recent advancements within the field.

Early T cell development

The thymus is seeded by progenitors sourced from the bone marrow

In the postnatal thymus, T cell precursors are derived from bone marrow (BM) resident hematopoietic stem cells (HSCs), which give rise to thymus seeding progenitors (TSP) that migrate into the thymus through the circulatory system and enter at the corticomedullary junction (Fig. 1) (Radojic and Maillard, 2016). This entry is mediated by the chemokines CCL19 and CCL21, which binds CCR7 on the surface of TSPs, as well as CCL25 which binds to CCR9 (Love and Bhandoolla, 2011). Following thymic entry, T cell progenitors undergo a series of developmental stages, which are demarcated by the expression of CD4 and CD8. In mice, the initial stage, characterized by the lack of expression of both CD4 and CD8, can be further broken down into four stages based on their expression of CD44 and CD25 (Fig. 1).

Recent work has further characterized the biology of TSPs as well as the factors involved in their differentiation from hematopoietic progenitor cells. Work conducted by Yu et al. demonstrated that deletion of the Osteocalcin-producing subset of BM stromal cells impairs T cell development despite having a normal thymus. Further investigation revealed that these BM stromal cells express Delta-like ligand 4 (Dll4), which serves to promote T lineage specification ahead of thymus entry, wherein Dll4-expressing thymus epithelial cells support T lineage commitment and further differentiation (Yu et al., 2015). The Dll4⁺ BM stromal cells likely serve to promote TSP generation in the BM prior to thymic seeding. Previously, it was believed that early thymocyte progenitors (ETPs) were derived from common lymphoid progenitors (CLPs) due to their similar phenotype (Radojic and Maillard, 2016). However, it has been shown that lymphoid-primed multipotent progenitors (LMPPs) appear to seed the

Fig. 1 T cell development occurs in various sections of the thymus. Early thymic precursors (ETPs) enter the thymus at the corticomedullary junction. Following entry, they migrate to the cortex as double negative (DN) 1 cells. DN1 cells interact with cortical thymic epithelial cells (cTECs), which provide a variety of signals to the developing thymocyte. Of note, cTECs express Delta-like ligand 4 (Dll4) and bind Notch1 on the surface of DN1 cells. Notch signaling promotes development and commitment of thymocytes in the early DN stages. As thymocytes develop they move to the outer edge of the cortex, while they rearrange their TCR β gene. At the DN3 stage, if there is a successful TCR rearrangement, the cells would receive signal through the pre-TCR which would allow for progression to the DN4 and double positive (DP) stage. However, if the TCR γ and TCR δ genes are successfully rearranged instead, the cell will develop into a mature $\gamma\delta$ T cell. By the DP stage, the cells have migrated towards the medulla and have rearranged their Tcr α gene. With a fully assembled TCR, DP cells interact with MHC on the surface of cTECs. DP cells that have a TCR specific to NKT or MAIT cells recognize non-classical MHC molecules on the surface of other thymocytes and develop into their respective cell. Cells that are able to successfully bind MHC at an appropriate affinity receive survival signals and continue development. Based on the class of MHC that the TCR is capable of recognizing, the cell develops into either a CD4 or CD8 T cell and migrates into the medulla. Once in the medulla, cells migrate between medullary TECs (mTECs) and dendritic cells and sample tissue restricted peptide expressed on the MHC of these cells. Thymocytes that react too strongly are eliminated through negative selection. Following selection processes, thymocytes leave the thymus as naïve T cells.

embryonic thymus (Luis et al., 2016). Lymphoid development has also been shown to arise from two distinct sets of progenitor cells, both derived from lympho-mono-dendritic progenitors (LMDP). Of the two, the subset that is CD127⁻ (IL-7R α) is thought to give rise to T cells (Alhaj Hussien et al., 2017). Additional research is needed to further define these progenitors and identify the exact subset of hematopoietic progenitors that give rise to TSPs (Chen et al., 2019).

PU.1 (*Spi1*) is expressed in these early progenitors and is critical for both the survival and development of T cells (Champhekar et al., 2015). Several factors have been recently identified as necessary in the promotion of thymic colonization (Alfaro et al., 2015; Lucas et al., 2016; Buono et al., 2016). Lymphotoxin- β receptor has been shown to regulate the expression of VCAM-1 and ICAM-1 in thymic epithelial cells (Lucas et al., 2016). These adhesion molecules were previously shown to be important for the colonization of thymocytes and their interaction with thymic epithelial cells (TECs) (Ehrlich, 2016). EphB2/B3 are a family of tyrosine kinase receptors that bind Ephrins, both of which are expressed by ETPs and TECs (Alfaro et al., 2015). Expression of EphB2 and EphB3 is necessary for the colonization of the thymus by ETPs and defective signaling of EphB2/B3 is associated with reduced expression of adhesion molecules and chemokines (Alfaro et al., 2015). This further illustrates their role in thymocyte seeding. Finally, early thymocytes in the CD4⁻ CD8⁻ double negative (DN) 1 and DN2 stage of development are characterized by expression of c-kit/CD117, however the source of its ligand kit-L/SCF was previously unknown (Buono et al., 2016). It was recently shown that membrane bound kit-L/SCF (mSCF) expressed on vascular endothelial cells (VECs) interacts with c-kit/CD117 on DN1 thymocytes, however DN2 cells instead interact with mSCF on the surface of TECs (Buono et al., 2016). This finding demonstrates a varying niche for early thymocyte entry and development.

Early thymocyte development is dependent on Notch signaling

Once TSPs have entered the thymus, they receive signaling from TECs that promote T cell development (Fig. 1). One of the major signaling molecules expressed on TECs is Dll4, which binds to the Notch-1 receptor on the surface of developing thymocytes (Radojic and Maillard, 2016). This ligand-receptor interaction culminates in the release of a Notch intracellular domain (NICD), which translocates to the nucleus and acts alongside various co-activators to promote the expression of genes associated with T cell development (Shah and Zúñiga-Pflücker, 2014). Using plate-bound Dll4 and VCAM-1, an in vitro niche was developed that was able to promote the development of the T-lineage cells from HSCs (Shukla et al., 2017). The role of VCAM-1 was thought to promote cell adhesion and amplify Notch-1 signaling. This demonstrated that activation of Notch-1 was sufficient to promote T cell development. Notch-1 is expressed prior to seeding of the thymus and its protein level is controlled post-transcriptionally through a suppressive domain in its 3'UTR (Mizuno et al., 2017). This regulatory region promotes expression of Notch-1 within the thymus.

Fringe proteins consisting of Lunatic, Manic and Radical Fringe are also necessary for the development of T cells. These proteins have been shown to modify the glycosylation of Notch-1, which affect its ability to interact with various Notch ligands, and deficiencies of all three Fringes resulted in impaired T cell development (Song et al., 2016). Studies have illustrated that Notch-1 signaling affects the expression pattern of several genes (Dos Santos Schiavinato et al., 2016; Hirano et al., 2015; Kobayashi et al., 2017). One of which is *Gata3*, which was shown to be important for T cell commitment (Mookerjee-Basu and Kappes, 2016; Radojic and Maillard, 2016). Notch-1 signaling directly promotes the expression of GATA3 (Dos Santos Schiavinato et al., 2016). In mice, the protein tyrosine phosphatase PRL2 is downstream of Notch signaling and has been shown to promote T cell development (Kobayashi et al., 2017). In addition, a recent study has demonstrated that the expression of c-Myc is able to promote T cell development from DN3 to DN4 (Hirano et al., 2015). This suggests that c-Myc is potentially one of the critical effector proteins downstream of Notch-1 signaling. Finally, the co-factor Zmiz1 has been shown to interact with Notch-1 directly to promote the DN to DP progression and proliferation (Wang et al., 2018).

DN3 onwards marks commitment to the T cell lineage

From the DN3 stage onward, thymocytes are committed to the T cell lineage and removal from the thymus will not enable differentiation to other lineages. One of the driving stimuli at this point in development arises from the successful V(D)J recombination of the β chain of the TCR. A fully rearranged β chain associates with pT α and CD3 to form the pre-TCR complex, which signals to promote survival and further differentiation (Mookerjee-Basu and Kappes, 2016). Although it is known that *Tcrd* and *Tcrg* rearrange at the same time as *Tcrb*, the significance of *Tcrd* rearrangements at this point in thymocyte development was attributed to an increased capacity to generate a broader repertoire of *Tcr* rearrangements at the DP stage (Carico et al., 2017). This early *Tcrd* rearrangement brings V α and J α regions in a more proximal orientation, which facilitates rearrangement. Thus, demonstrating distinct chromatin conformations at the DN and DP stage.

Recent studies have focused on the factors involved in driving differentiation downstream of the pre-TCR signal as well as factors that promote commitment to the T cell lineage. NFATc1 has been shown to be important for the promotion of both thymocyte survival and T cell commitment. It is regulated by two promoters, P1 and P2. P1 expression requires pre-TCR activity and it promotes differentiation of T cells (Klein-Hessling et al., 2016). In addition, phospholipase C γ (PLC γ) 1 has been shown to be activated by pre-TCR stimulation and functions similar to its role in mature TCR signaling (Fu et al., 2017). Deficiency in PLC γ 1 results in the inability, as thymocytes, to proceed from DN3 to DN4. Further study into the signaling of the pre-TCR has demonstrated that a specific sequence within the CD3 ITAM domains is necessary for DN4 to double positive (DP) transition. In addition, the 10 ITAM domains of CD3 must consist of a $\gamma\epsilon$, a $\delta\epsilon$ and a $\zeta\zeta$ dimer; as other combinations showed reduced cellularity within the thymus (Bettini et al., 2017). Importantly, a recent study demonstrated that the expression of Lck-Cre as a homozygous transgene in mice resulted in defects in thymocyte development. Alterations included reduced DN to DP transition and increased frequencies of $\gamma\delta$ and regulatory T cells (Carow et al., 2016). These alterations can be addressed by using Lck-Cre⁺ T cells as controls, and it should be considered when interpreting data.

Generally, DN thymocytes are dependent on a number of survival signals for proliferation and progression through the T cell lineage developmental program, such as IL-7 (Wang et al., 2016). A recent study demonstrated that conditional deletion in TECs of the gene encoding the protein Rictor, a component of the mTORC2 signaling pathway, induced a large decrease in T cell populations and thymic atrophy (Wang et al., 2016). This suggests that the signals induced by mTORC2 are necessary for the survival of TECs and therefore indirectly, developing thymocytes. Recent studies have demonstrated an important role for epigenetic modifications in the early development of thymocytes. Kat7 is responsible for the maintenance of histone 3 lysine 14 (H3K14) acetylation and was found to be necessary for the development of both conventional and innate-like T cells (Newman et al., 2017). In addition, deficiency of histone deacetylase (HDAC) 3 resulted in an impaired development of DP thymocytes. This phenotype was remedied by the addition of a fully rearranged TCR $\alpha\beta$ transgene (Stengel et al., 2015; Philips et al., 2016). Therefore, it is likely that HDAC3 plays a role in TCR β rearrangement for the transition into the DP stage. In addition, HDAC3 inhibits P2X7, a receptor associated with cell death, and restrains the genes associated with CD8 commitment during the DP stage (Philips et al., 2019a,b). This ensures proper development and cellularity during the DP stage. In addition, ESET is a histone methyltransferase associated with the addition of methyl groups to lysine 9 on histone 3 (H3K9Me) and its deletion resulted in the impairment of thymocyte development through the inhibition of the ERK signaling pathway. H3K9Me often serves to inhibit gene expression, and one of the genes inhibited in T cells is Fc γ RIIb, which has been shown to inhibit the ERK pathway (Takikita et al., 2016), demonstrating the

downstream effect that ESET can have on T cell development. Finally, TCF1 and HEB have been shown to cooperate to establish transcriptional and epigenetic regulation at the DP stage (Emmanuel et al., 2018). Taken together, epigenetic regulation has a clear role in T cell development and further study of epigenetic regulation is imperative for understanding the process.

Selection of thymocytes

Positive selection selects for TCR-MHC interaction

In the DP stage, the cells rearrange their alpha TCR chain and following successful rearrangement, the cells express a mature TCR on their surface and undergo positive selection. Positive Selection is a process that occurs at the DP stage soon after the formation and expression of a fully functional $\alpha\beta$ -TCR (Koehli et al., 2016). Thymocytes sample peptide antigens presented on self-MHC on the surface of cortical TECs and low-affinity TCR binding to peptide-MHC promotes survival of thymocytes (Fig. 1) (Koehli et al., 2016; Neier et al., 2019). At this time, extreme TCR signals outside of this necessary low affinity signal, will result in the death of the cell. Self-peptide presented during positive selection is processed through the thymoproteasome and components such as $\beta 5t$ (*PSMB11*) orchestrate efficient development of DP cells (Apavaloaei et al., 2019; Tomaru et al., 2019). Expression of $\beta 5t$ outside of the cortex of the thymus leads to aberrations in development and increased autoimmunity (Tomaru et al., 2019). These findings support the hypothesis in which the thymoproteasome produces unique self-peptides for the sole purpose of positive selection. This ensures that mature T cells can recognize antigens in the context of self-MHC while preventing the development of a bias towards self recognition within the TCR repertoire. Special AT-rich binding protein 1 (SATB1) is a chromatin regulator that is upregulated in response to TCR signaling and its activity has been associated with positive selection in thymocytes (Gottmukkala et al., 2016). This evidence further supports the fact that TCR activation promotes positive selection.

Recent studies have identified Themis, a protein which is upregulated during positive selection (Garreau et al., 2017). Themis associates with the proteins SHP-1 and Grb2 during positive selection in thymocytes (Choi et al., 2017; Garreau et al., 2017; Paster et al., 2015; Radtke et al., 2016). Themis stabilizes Grb2 allowing it to bind to LAT and recruit the complex to the plasma membrane in proximity to the TCR (Garreau et al., 2017; Paster et al., 2015; Zvezdova et al., 2016). SHP-1 is a tyrosine phosphatase that removes phosphates from ITAM motifs (Martinez et al., 2016). Themis acts as a regulator of SHP-1 to inhibit its phosphatase activity during positive selection (Choi et al., 2017; Mehta et al., 2018). Therefore, Themis acts to reduce the binding threshold needed for TCR activation during positive selection, allowing for TCR activation in response to weak affinity peptide-MHC (pMHC) interactions. Protein kinase D (PKD) is activated in DP cells, and phosphorylates SHP-1, promoting positive selection (Ishikawa et al., 2016). Whether phosphorylation directly inhibits SHP-1 or plays a role in Themis regulation remains to be determined. Grb2 is also found to recruit USP9x to LAT, where it acts to stabilize Themis (Garreau et al., 2017). Finally, CD6 is an adhesion molecule that binds ALCAM/CD166 on the surface of antigen presenting cells (APCs). CD6 deficiency impairs T cell development and lowers regulatory T cell populations (Orta-Mascaró et al., 2016). Generally, these factors function to improve the efficacy of positive selection. However, miRNA-146a has been shown to inhibit NF κ B and other genes associated with positive selection (Li et al., 2018).

Positive selection promotes the production of single positive CD4 and CD8 cells based on affinity for MHC class II or class I, respectively (Koehli et al., 2016). In addition, recent contributions have led to a greater understanding of the molecular factors that influence the development of either subset. Runx3 promotes the development of CD8 single positive T cells, whereas ThPOK promotes the development and commitment of CD4 single positive T cells (Mookerjee-Basu and Kappes, 2016). In CD8⁺ cells, duration of positive selection was similar, independent of TCR-pMHC half-life, however, longer TCR signaling was accompanied by quicker Runx3 induction (Kimura et al., 2016). In addition to γ chain (γ_c) cytokines, primarily IL-7, influencing the development of T cells, non- γ_c cytokines including IL-6 and IFN- γ are associated with the expression of Runx3 (Etzensperger et al., 2017). Therefore, these cytokines support and promote the development of CD8⁺ T cells. Finally, the TLE co-repressors were demonstrated to be imperative for the commitment of CD8⁺ T cells. TLE3, in particular, was shown to bind ThPOK silencer to inhibit the expression of CD4 and related genes (Xing et al., 2018). In contrast, the Ikaros family of proteins, expressed during the transient single positive (TSP) stage, are important for the establishment of single positive cells. CD4 expression is associated with a decrease in Helios and an increase in Ailos (Mitchell et al., 2016). UBC9 modifies NFAT and IL-7 signaling through SUMOylation and is required for efficient development of T cells following positive selection (Wang et al., 2017a).

Negative selection removes auto-reactive T cells

Following positive selection, single positive thymocytes migrate from the cortex into the medulla of the thymus by CCL19/21 chemokine gradients and undergo negative selection, which is a critical component of central tolerance (Fig. 1) (Koehli et al., 2016). Thymocytes sample the autoantigens presented by medullary (m)TECs and medullary DCs, and a strong response to autoantigen triggers the death of the potentially offending T cell (Fig. 1) (Ehrlich, 2016). Nuclear receptor corepressor 1 (NCoR1) has been shown to repress apoptosis induced in negative selection by inhibiting the pro-apoptotic factor BIM (Müller et al., 2017; Wang et al., 2017b). Therefore, this raises the threshold of activation required for the negative selection of thymocytes. This ensures that primarily auto-reactive T cells are eliminated before final maturation. Finally, mechanotransduction loops through the TCR have been indicated in playing a role in negative selection (Hong et al., 2018). Deficiencies in negative selection and central tolerance are heavily associated with auto-immune disease (Koehli et al., 2016). By analyzing the selection pattern associated with known TCRs, it has been shown that the majority of negatively selected TCRs are promiscuous receptors that broadly recognize auto-antigen (McDonald et al., 2015).

During negative selection, thymocytes must migrate between stromal cell niches (Hu et al., 2015; Ki et al., 2017). The chemokine receptor, CCR4, is expressed on thymocytes following positive selection and its ligand is secreted by medullary dendritic cells (mDCs), an APC involved in negative selection. This receptor, alongside CCR7, promotes the entry of thymocytes into the medulla and is necessary for efficient negative selection (Hu et al., 2015). Recently, CCR8 was also identified on the surface of positively selected CD4 thymocytes and its ligand is produced by medullary cells. However, its function was not required for medullary entry (Thyagarajan et al., 2018). This could be explained by redundancy or potentially an alternative role for CCR8. In mouse models, EBI2 is expressed by CD4⁺ T cells and deletions impair migration during negative selection, while also altering the final TCR repertoire (Ki et al., 2017). This indicates that EBI2 is important in mediating the migration of thymocytes during negative selection.

In addition to migration patterns, the thymic medulla is unique due to its expression of autoantigens normally restricted to specific cell types (Kawano et al., 2015; Takaba et al., 2015). The expression of tissue restricted antigens (TRA) in the thymus facilitates T cell exposure to a larger variety of antigens that may be encountered in the periphery. Aire is a transcription factor that is expressed in mTECs and regulates the expression of TRAs as well as adhesion molecules and conditional deletion of Aire gives rise to auto-immune disease (Haljasorg et al., 2015; Pezzi et al., 2016). Recent work has identified a region upstream of the *Aire* gene called CNS1, which contains two NFκB binding sites, deletion of this region results in a similar phenotype to Aire deletion (Haljasorg et al., 2015). Therefore, NFκB likely serves as a regulator of Aire. In addition, Aire was found to be expressed in over 95% of mTECs, however only a small subset of mTECs expressed Aire at one time (Kawano et al., 2015). This would suggest that Aire is temporally regulated. In addition, the expression of TRAs requires specific epigenetic chromatin remodeling that occurs early in mTEC development (Handel et al., 2018). This development is Aire-independent.

Recently, Fezf2 has also been found to promote the expression of TRAs in mTECs, and deletion induced severe autoimmunity (Takaba et al., 2015). Further demonstrating the importance of TRAs in negative selection. Similar to their role in positive selection, Themis, SHP-1 and Grb2 have been found to promote the negative selection of thymocytes (Martinez et al., 2016; Paster et al., 2015). During negative selection, SHP-1 activity attenuates TCR signaling and promotes survival (Martinez et al., 2016). Therefore, the Themis complex functions to modify the TCR signaling threshold necessary for both positive selection and negative selection. Additional research will aid to elucidate what factors are involved in the complex function that Themis has on TCR signaling.

Occasionally, when a TCR exhibits a high affinity for self MHC/peptide, rather than being eliminated, the T cell can be selected to act as a regulatory T cell through the process of agonist selection (Fig. 1) (Koehli et al., 2016; Kitagawa and Sakaguchi, 2016). Regulatory T cells are a component of peripheral tolerance and function to generate an immunotolerant environment to self antigens (Kitagawa and Sakaguchi, 2016). Recent studies have shown that deletion of pro-apoptotic factor BIM results in an increase in the development of agonist-selected T cells (Hu et al., 2017; Li et al., 2017a,b). BIM likely serves to eliminate auto-reactive T cells with an affinity that surpasses the threshold necessary for agonist selection.

Unconventional T cell development

Regulatory T cell development

Regulatory T (T_{reg}) cells are a subset of CD4⁺ T cells which act as the central component of peripheral tolerance (Kitagawa and Sakaguchi, 2016). Generally, these cells regulate homeostasis by impairing effector activation. One method involves the production of anti-inflammatory cytokines such as IL-10 in response to autoantigens, impairing autoreactivity of effector T cells (Kitagawa and Sakaguchi, 2016). Natural T_{reg} (nT_{reg}) make up the majority of T_{reg} cells and this subset develops within the thymus as a result of agonistic selection. Recent evidence suggests that nT_{regs} can be divided into two groups characterized as either CD25⁺ or FoxP3^{low} and these unique types develop from two distinct pathways (Owen et al., 2019). In addition to nT_{regs}, there is a subset that develops in the periphery from naïve T cells referred to as induced T_{reg} (iT_{reg}) cells (Kitagawa and Sakaguchi, 2016). High salt conditions have been found to inhibit the development of nT_{regs}, while having no effect on iT_{reg} (Luo et al., 2019). Further illustrating two distinct mechanisms of development. Early development of nT_{reg} cells occurs in a fashion similar to CD4⁺ effector T cells with differentiation between the subsets occurring in the DP stage of thymocyte development. Evidence has shown that competition among nT_{reg} cells can inhibit their differentiation, resulting in the production of effector T cells (Kitagawa and Sakaguchi, 2016), demonstrating the overlap in their development. During the DP stage, thymocytes undergo selection in which T cells with a high affinity to self-antigen are removed from the population, however some auto-reactive T cells are selected for and differentiate into nT_{reg} cells (Kitagawa and Sakaguchi, 2016). Recently, the cytokines IL-7 and IL-2 has been found to promote the development of nT_{regs} during the DP stage (Tuulasvaara et al., 2016; Chorro et al., 2018). IL-2 was found to regulate SATB1, which controls chromatin accessibility in developing cells (Chorro et al., 2018). Agonistic selection induces the expression of FoxP3 which acts as the master transcription factor for the T_{reg} phenotype. Past studies have demonstrated that FoxP3 is important for both the development and function of T_{reg} cells. FoxP3 is capable of promoting the survival of regulatory T cells during negative selection by upregulating the expression of CTLA-4 on the cell surface that binds to CD80/86 and competes with CD28, a co-stimulatory molecule for TCR activation (Kitagawa and Sakaguchi, 2016). It has also been shown to downregulate the expression of ZAP-70, an important component in the transduction of TCR signals (Kitagawa and Sakaguchi, 2016). This evidence would suggest that FoxP3 can induce T_{reg} survival during negative selection by reducing the intensity of TCR activation. In addition, a region in FoxP3 was shown to directly regulate genes associated with the T_H2 phenotype and mutations in this region led to the de-repression of these genes (Van Gool et al., 2019).

Studies on the development of regulatory T cells have identified molecular factors, in addition to FoxP3, required for their development. Adhesion molecules have been shown to be important for promoting TCR activation and ICAM-1 specifically has been shown to play a role in nT_{reg} development (Gotttrand et al., 2015). In addition, thymic PLZF⁺ innate T cells have been shown to promote the differentiation of CD103⁺ regulatory T cells, which display an activated phenotype, through the production of IL-4 (Kang et al., 2016). Finally, a study conducted by Feng et al. demonstrates a FoxP3 intronic enhancer, CN3, which is necessary for the induction of FoxP3 in the development of nT_{reg} cells but is not necessary in maintaining its expression in mature cells (Feng et al., 2015). Further analysis has shown that this region is epigenetically modified with H3K4Me. This modification occurs early in T cell development and can be added as early as the DN1 stage (Feng et al., 2015). These modifications enhance the cell's sensitivity to FoxP3 induction and are required for a diverse T_{reg} repertoire. Deletion of this domain has been shown to reduce the proportion of regulatory T cells and drastically affect their diversity (Feng et al., 2015). These results provide a potential explanation for how a large variety of TCRs can be found within the population of T_{reg} cells despite the fact that a limited range of TCR affinities are selected to differentiate into regulatory cells.

γδ T cell development

The TCR found on conventional T cells is a heterodimer composed of an α chain and a β chain. However, there exists an alternative class of T cells which contain a TCR composed of a γ chain and a δ chain (In and Anderson, 2016). γδ T cells possess an innate-like phenotype and their development is unique in comparison to conventional T cells (In and Anderson, 2016). γδ T cells proceed through a similar development program as conventional T cells until the DN3 stage (Fig. 1). At this stage, γδ T cells express a fully formed TCRγδ, which provides alternative signaling compared to the pre-TCR found on conventional T cells (In and Anderson, 2016). However, recently a unique class of γδ T cells has been shown to develop from DN2a thymocytes. These cells develop independent of Bcl11b, which is a transcription factor necessary to promote progression from DN2a to DN2b (Hatano et al., 2017). In addition, recent work has demonstrated the role of selecting ligands in shaping the γδ repertoire (Fahl et al., 2018). Finally, PTPN2 is a tyrosine phosphatase that attenuates STAT5 signaling and has been shown to influence T cell commitment, as well as the differentiation between conventional and γδ T cells. Deficiency in PTPN2 has been shown to repress the γδ developmental pathway (Wiede et al., 2017). Additional research should be conducted to understand what factors are involved in the differentiation of these two T cell lineage subsets.

γδ T cells are classified based on the variable region within their TCR as well as their effector function (In and Anderson, 2016), and these effector functions share similarities with the subsets of conventional T cells. The IL-17 producing class of γδ T cells has been shown to rely on different survival factors than the IFN-γ producing cells (Corpuz et al., 2016). Therefore, it is likely that these groups do not share a common niche and likely do not compete for survival. Recent advancements have improved upon the current understanding of what factors influence the development of each γδ T cell subset. Work conducted by Buus et al. has mapped out seven different developmental stages of γδ T cells using CD117, CD200 and CD371 as markers. These stages are labeled A through G and the development of three distinct subsets (IFNγ, IL-4 and IL-17 producing cells) can be mapped using these stages (Buus et al., 2017). Factors involved in the development of IL-17 producing γδ T cells have also been elucidated. HEB has been shown to be required for the expression of RORγT in fetal γδ T cells and promotes the production of related cytokines such as IL-17 (In et al., 2017). In addition, it has been shown that a strong TCR signal inhibits the development of IL-17 producing γδ T cells (Sumaria et al., 2017; Zarin et al., 2018). This supports the previous hypothesis that strength of signaling may play a role in determining γδ T cell subsets. In addition, evidence has demonstrated that IL-17 producing cells are capable of developing extra-thymically. During this process, IL-1β and IL-23 convert CD122⁻ γδ T cells into IL-17 producing cells (Muschawek et al., 2017; Zarin et al., 2018). This evidence suggests that γδ T cell subsets may possess plasticity in the periphery. Finally, it has been shown that subsets expressing Vγ1.1 and Vγ2 diverge at a later stage than previously thought. This divergence occurs after γδ commitment and can be tracked by the expression of CD73 (Coffey et al., 2014). Prior to diversification, these two subsets contain very similar transcriptomes (Buus et al., 2016). In addition, TCR, Notch and cytokine signaling have all been demonstrated to play a role in specifying the various functions of γδ T cells (Zarin et al., 2018). As a whole, it is evident that γδ differentiation is extremely complex and multiple factors are required for the development of each effector function.

Mature double negative TCR-αβ T cells

Double negative T cells are mature cells that lack the expression of the co-receptors CD4 and CD8 (Lamboleze and Cheroutre, 2016). These cells are associated with the intestinal epithelia. During development these cells are selected through agonist selection and can provide immunosuppressive effects. The addition of IL-7 has been shown to inhibit the immunosuppressive function of double negative (DN) T cells through the Akt/mTOR signaling pathway (Lamboleze and Cheroutre, 2016). Overall, the development of these T cells is not well understood other than what has previously been outlined, however recent work conducted by Chowdhary et al. provides a model that could potentially be used to further the understanding of their development. In their experiment, they induced a double knock out of CD4 and CD8 in T cells, then analyzed the phenotype of the affected mice. They found that this simulated the DN T cell phenotype in the periphery and demonstrated DN T cell's role in pathologies such as lupus (Chowdhary et al., 2017). Finally, an additional study has demonstrated that a population of DN T cells develop from autoreactive CD8⁺ T cells. These cells are often short lived but may play a significant role in DN T cell function (Rodríguez-Rodríguez et al., 2016).

NKT cell development

NKT cells are an unconventional class of T cells that have an innate-like phenotype and share similar features with NK cells. These cells have been shown to recognize lipids presented by the non-classical MHC, CD1d. Past studies have demonstrated two types of NKT cells, type 1 or invariant (iNKT) and type 2 which are variant in their TCR. Invariant NKT cells are characterized by the expression of a semi-invariant TCR consisting of V α 14 and J α 18 in mice. These TCRs contain a hydrophobic region that is necessary for CD1d interaction and NKT development (Vieth et al., 2018). Similar to conventional T cells, iNKTs have been shown to possess different functional subsets that produce cytokines such as IFN- γ , IL-4 or IL-17. Recent advancements have focused on understanding the developmental pathway of iNKTs and how their development differs from conventional T cells. Previously, NKT cells have been shown to diverge from conventional T cells at the DP stage, through selection on thymocytes (Fig. 1). However, it has recently been shown that some NKT cells may diverge from the conventional program at the DN rather than the DP stage (Dashtsoodol et al., 2017). In addition, previous work on iNKT development has demonstrated a reliance on miRNA for their development, however the identity and function of these miRNAs were unknown (Blume et al., 2016; de Candia et al., 2016; Frias et al., 2018). Recently, it has been shown that miR-181a/b-1, which is induced by SOX4, functions to tune TCR signaling and is necessary for the development of iNKT cells. In mice deficient for miR-181a/b-1, NKT development was severely impaired, and this impairment could be rescued by the overexpression of V α 14J α 18 TCR transgene (Blume et al., 2016; de Candia et al., 2016; Malhotra et al., 2018). This supports the hypothesis that miR-181a/b-1 acts to promote agonist selection of NKT cells by lowering the TCR activation threshold and therefore promoting their development. TCR activation has also been associated with development of certain subsets of NKT cells (Clancy-Thompson et al., 2017; Cruz Tleugabulova et al., 2016; Tuttle et al., 2018). Strong stimulation of the TCR has been linked to the downregulation of Id2 (Stradner et al., 2016), and Id proteins have been shown to regulate the expression of E2A, which is critical for NKT development (Roy et al., 2018). In addition, Id2 deficiency is associated with decreased expression of T-bet and increased expression of PD-1 (Stradner et al., 2016). However, a double KO of Id2 and Id3 induces rapid growth in NKT cells associated with NKT tumors (Kumar et al., 2017). This suggests that Id proteins may serve multiple and distinct purposes in NKT cells. A higher TCR affinity has also been shown to correlate with increased expression of PLZF and reduced expression of T-bet (Clancy-Thompson et al., 2017). The negative regulatory protein of the NF κ B pathway, TNFAIP3/A20, is downstream of the TCR signaling pathway and a deficiency in this protein results in hyper-reactive NKT cells. In addition, its expression has been shown to influence the development of both IFN- γ producing (NKT1) and IL-4 producing (NKT2) cells (Drennan et al., 2016). This phenotype can be reversed through a deficiency in a member of the NF κ B activation pathway, MALT1. This further illustrates the dependence of TCR signaling on NKT subset development. Overall, the level of TCR signaling is critical for the development of NKT cells. However, the TCR is not the sole contributor to NKT cell development and it has previously been shown that γ chain cytokines are critical for the development of T cells, including NKTs. Recently, arginine methylation by the enzyme PRMT5 has been shown to modulate the strength of cytokine signaling. This enzyme is particularly critical for the development of NKT cells, as deletion of PRMT5 leads to the loss of NKT cells (Inoue et al., 2018). In addition, SHP-1 was shown to regulate iNKT cell differentiation in a TCR-independent manner (Cruz Tleugabulova et al., 2019). In this scenario, it is likely that SHP-1 adjusts NKT cell response to cytokines within their environment. The environment that the NKT cell is exposed to has been shown to influence its maturation. In somatic nuclear transfer studies, the cytokine profile of monoclonal NKT cells was heavily influenced by their tissue localization, despite having identical TCRs (Clancy-Thompson et al., 2017).

Recent work has also demonstrated a strong epigenetic influence on the development of NKT cells (Beyaz et al., 2017; Cui et al., 2016; Northrup et al., 2017; Thapa et al., 2017; Tsagaratou et al., 2017). Histone Demethylase UTX is necessary for the expression of NKT associated genes, specifically PLZF (Beyaz et al., 2017; Northrup et al., 2017). In addition to demethylases, HDAC3, a histone deacetylase, has been shown to be critical, both for the development of NKT cells as well as the production of IL-4 and IL-17 (Thapa et al., 2017). Finally, Uhrf1 is a regulator of DNA methylation and is upregulated during stage 1 of iNKT cell development (Cui et al., 2016). Uhrf1 promotes survival through the Akt-mTOR pathway, which has previously been shown to be necessary for NKT cell survival (Cui et al., 2016). This is further illustrated in the fact that a conditional deletion of Rictor, a protein associated with the mTORC signaling pathway, results in the loss of NKT17 development (Sklarz et al., 2017). The development of NKT cells is also associated with the phenotype of the cells around them. ABCA7 is an ABC transporter and loss of function mutations are associated with reduction of CD1d expression and alterations in lipid rafts (Nowyhed et al., 2017). This extrinsically affects NKT cells by reducing the amount of CD1d available.

CD1d is critical for the selection of NKT cells, and different variants of CD1d possess unique roles in the development of effector functions (Sundararaj et al., 2018). Production of sphingolipids (SL) in cells is also necessary for proper NKT development. In cells deficient for ceramide synthases, SL production is impaired, and this results in a reduced number of NKT cells (Popovic et al., 2017; Saroha et al., 2017). SLs likely function as an endogenous ligand to be presented during selection. Previous entries have defined the importance of SLAM-SAP interaction between thymocytes and NKT cells during selection (Chen et al., 2017). Recently, SLAM receptor alterations have been shown to lead to changes in the expression of Ly108, CD150 and Ly9. Ly108 is especially important since it is necessary for the activation of NKT cells (Baglaenko et al., 2017). SAP deletions in NKT cells decrease the expression of GATA-3 and PLZF while promoting the expression of ROR γ T (Michel et al., 2016). This results in reduction of NKT2 numbers and IL-4 production, while increasing NKT17 numbers. It is evident that NKT development relies on the phenotype of the cells around it, both during selection and maturation.

PLZF is a transcription factor necessary for the innate phenotype in many unconventional T cells and it is important for NKT cell maturation, and recent work has led to a greater understanding of PLZF's role in development. An analysis of the targets of PLZF have

established a temporal hierarchy of PLZF activation. Initially, PLZF acts to regulate the expression of cytokine receptors and adhesion molecules, it then regulates transcription factors associated with effector functions and finally it suppresses Bach2, a repressor of effector functions (Mao et al., 2016). This further demonstrates PLZF's role in promoting innate effector function. Evaluation of the region upstream of PLZF has identified regions homologous to RUNX1 motifs and deletion of RUNX1 resulted in reduced PLZF expression in these cells (Mao et al., 2017). The protein YY1 has also been shown to be critical for NKT development, and directly binds regions of the PLZF gene (Ou et al., 2019). In addition to our increased understanding of PLZF, recent work has revealed other proteins associated with the development of NKT cells. β -Catenin has been shown to be temporally regulated in NKT cells. The protein is initially expressed during development but downregulated in stage 2 and failure to reduce the expression of β -Catenin results in impaired transition to stage 3 (Pyaram et al., 2017). Roquin, a class of mRNA binding protein, has been shown to be a regulator of NKT cell development in mice. Impairment of Roquin leads to impaired cytokine production and increased NKT17 development (Drees et al., 2017). In addition to Roquin, c-MAF and NKAP have been shown to be necessary for proper NKT17 development and function (Thapa et al., 2016; Yu et al., 2017). Finally, CD69 has been shown to be critical for the retention of NKT cells in the thymus. Cells deficient for CD69 prematurely express S1P1R and abort NKT2 development (Kimura et al., 2018). Therefore, the various subsets of NKT cells require different factors for development and further research must be conducted to understand these pathways.

MAIT cell development

Mucosa associated innate T (MAIT) cells are a recently described T cell that, similar to NKT cells, recognizes antigen in the context of a non-classical MHC class 1b (MR1). As their name implies, MAIT cells are found primarily in the mucosa and possess an innate phenotype (Leeansyah et al., 2014). MAIT cells are capable of recognizing vitamin B2 metabolites from bacteria which are presented on MR1 molecules (Rahimpour et al., 2015). This allows for the recognition of a broad spectrum of bacteria. They have been shown to produce IFN- γ and IL-22 in response to antigen (Rahimpour et al., 2015). Recent advancements in the understanding of MAIT cells can be attributed to the development of MR1 tetramers, which can be used to identify MAIT cells using flow cytometry (Rahimpour et al., 2015; Gherardin et al., 2018). MAIT cells develop in the thymus and are positively selected by thymocytes expressing MR1 (Fig. 1) (Seach et al., 2013).

After selection, MAIT cells proceed through three developmental stages similar to NKT cells. Each stage is characterized by their expression of CD24 and/or CD44. Stage one and two of development occurs entirely in the thymus, while stage three cells are initially found in the thymus, but complete maturation extrathymically. Deletion of MR1 in T lineage cells prevents the progression of MAIT cells through the various stages (Koay et al., 2016). This would suggest that MR1 is necessary for checkpoint transition of each stage. Secretion of IFN- γ and IL-22 is only found once the cells have progressed to stage three. This is also the stage where PLZF is expressed. PLZF is a transcription factor associated with innate programming in lymphocytes and is necessary for MAIT cell maturation. Through co-culture with OP9 cells, Koay et al. demonstrated that stage 3 of MAIT cell development requires stromal factors. It was also shown that Dll is initially required for DN development but not required later in MAIT cell-specific development. In addition, the knock outs of DROSHA or DICER, machinery associated with the production of miRNA, inhibited the development of MAIT cells. This would suggest that MAIT cell development is dependent on the production of miRNAs that likely play a direct role. Maturation of MAIT cells is dependent on the presence of microbiota in the gut. This relationship occurs through IL-18 produced as a result of the microbiota. MAIT cells upregulate IL-18R during development and signaling through this receptor promotes development (Koay et al., 2016).

Characterization of the development of MAIT cells demonstrates many similarities with NKT cells. For one, both cells recognize antigen in the context of MHC class 1b and display an innate phenotype. In addition, both cell types are positively selected by thymocytes rather than TECs (Seach et al., 2013). This similarity is further exemplified by the observation that deletion of CD1d leads to an increase in the proportion of MAIT cells (Koay et al., 2016). Since CD1d is necessary for the development of NKT cells but not MAIT cells, this would suggest that these two cell types share a resource niche. However, NKT cells leave the thymus as mature innate cells whereas MAIT cells leave the thymus as naïve cells and complete maturation in the periphery. Evidence suggests that one of the more common MAIT cell phenotypes which express CD8 $\alpha^+\beta^-$ exits the thymus and develops extrathymically (Leeansyah et al., 2014). Recently, a subset of MAIT cells has been characterized that is negative for both CD4 and CD8. These cells are functionally distinct from the conventional CD8 $^+$ MAIT cells, but evidence suggests that chronic TCR stimulation induces development of DN MAIT cells from CD8 $^+$ cells (Dias et al., 2018).

Conclusion and future directions

Based on recent findings, presented above, the complexity of T cell development is even more apparent. However, the past few years have improved our understanding of features in both conventional and unconventional T cell development. Work conducted in the aspects of selection have demonstrated Themis' ability to modulate the threshold of TCR activation required during selection. It has also shown the importance of factors such as Aire and Fezf2 in maintaining effective negative selection. Recent work into unconventional T cells has led to a greater understanding of their development as well as the characterization of MAIT cells. Further research should focus on the mechanisms involved in determining one developmental pathway over another. Special interest should be placed on the development of unconventional T cells, since many of these cells have only been described recently and their development is still poorly understood.

Introduction

Any substance (molecule) capable of inducing a specific immune response (humoral or cellular) against that substance, or can be recognized by products of an immune response, such as antibodies or lymphocytes, is commonly called an antigen. Antigens exist in many forms: typically they can be simple molecules, toxins, chemicals, proteins, carbohydrates, lipids or nucleic acids derived from invading microorganisms, such as viruses, bacteria, protozoans, and fungi, or other foreign substances that are usually not found in the body (non-self or heteroantigens). In addition, the body's tissue and cells, including cancer cells, can also have antigens (self or autoantigens, or mutated neoantigens) in them and can cause an immune response (Zamvil et al., 1986; Khodadoust et al., 2017). These autoantigens can be used as biomarkers to identify those specific tissues or cells (Schumacher and Schreiber, 2015; Balachandran et al., 2017). Although antigens exist in numerous forms, they all share a common mechanism of triggering an immune response. The immune system in humans and other mammals can be divided into two general categories: the *innate*, which is a more general immune system that can recognize foreignness, but not specific antigens, and the *adaptive*, which is more a specialized immune system with receptors for specific antigens. These two systems work closely together and take on different tasks—while the innate immune response is immediate, the adaptive immune response is not. However, the effect of the adaptive immune response is long-lasting, highly specific, and manifests sustained long-term memory (Janssen et al., 2003; Polonsky et al., 2018).

When an antigen binds to a receptor molecule, it may or may not initiate an immune response. Antigens that have an ability to induce an effective humoral and/or cellular immune response following immunization are called immunogens. This ability to elicit an immune response is referred to as *immunogenicity*. Immunogenicity and antigenicity are related, but are distinct, immunologic properties that sometimes are confused. Antigenicity is the property of being able to be recognized by the immune system, perhaps a pre-existing immune response or its product like an antibody or T cell. It does not require that they be able to elicit that response. All immunogens are antigenic, but not all antigens are immunogenic. In other words, all molecules that possess the property of immunogenicity also possess the property of antigenicity, but the reverse is not true—not all antigens are immunogens. For example, some small molecules called haptens possess the property of antigenicity (can bind to lymphocyte receptors) but do not induce a specific immune response (by themselves). In other words, haptens lack immunogenicity. Although haptens cannot induce an immune response by themselves, they can become immunogenic when joined to a larger and more immunogenic molecule, called a carrier (Martin and Weltzien, 1994). Immunization with hapten-carrier combination elicits an immune response to both hapten and carrier (Boak et al., 1971). Details of haptens will be discussed later in this chapter.

Fig. 1 Diagram of antigen-antibody recognition. Antigens can have multiple epitopes that can be recognized by specific antibody. The antigen-antibody interaction take place between the epitope of the antigen and paratope of the antibody.

Antigens can have several distinct 3D structural patterns on their different surface areas. Each pattern is called an antigenic determinant, or epitope, defined as the portion of the antigen recognized by an antibody or T cell. Each epitope, which is usually made of 6 to 20 amino acids or 1–6 sugars in a polysaccharide, determines the specificity of the antigen-antibody reaction, as usually the antibody binding site cannot accommodate the whole antigen. Thus, the immune system recognizes specific epitopes of the antigen (Fig. 1). There may be multiple epitopes per molecule (Baumhüter et al., 1987; Sahin et al., 2017). Some epitopes are more immunogenic than others. Complex antigens can evoke responses from a variety of specific lymphocytes. Also, it is possible for two or more different antigens to have an epitope in common. In these cases, the immune response induced by one antigen is capable of reacting with the other antigens (cross-reacting antigens) carrying the same or a closely homologous epitope (Wilson et al., 2001; Yewdell et al., 1985). However, in some cases, certain antibodies can distinguish native vs denatured conformational forms of the same protein because they recognize a particular 3D conformation, not just a linear amino acid sequence (e.g., myoglobin, gp160 protein of HIV) (Wrapp et al., 2020; Gorny et al., 2002; Montefiori et al., 1993).

The initiation of durable antigen-specific immune responses requires the activation of T and B lymphocytes, given that they are the only cells able to recognize and respond specifically to each antigenic epitope. T cells recognize antigens through the T-cell receptor (TCR) on their surface, after the antigen has been processed into small fragments and presented on major histocompatibility complex (MHC) molecules (class I, class II, or MHC-like molecules, CD1 molecules, in case of lipids, and MR1 molecule, in case of Vitamin B metabolites or precursors) by antigen presenting cells (APCs), such as dendritic cells (DCs), macrophages, and B cells (Fig. 2; Germain and Margulies, 1993; Chandra and Kronenberg, 2015; Cohen et al., 2009). These T cells either mediate effector functions directly as killer T cells or go on to activate effector cells, as helper T cells activate B-cells or cytotoxic T cells. B cells are activated when their B cell receptor (BCR) on their surface binds to either soluble or membrane-bound antigens. B cells have the ability not only to transform into plasmocytes to produce antibodies but also to act as APCs, although DCs are the primary professional APC (Steinman, 1991; Banchereau and Steinman, 1998). The humoral immune response depends on the B cells while the cellular immune response depends on the T cells (Planz et al., 1997). The capacity of antibodies to recognize specific antigen epitopes resides in their functional binding sites or *paratopes* (Fig. 1). Thus, paratopes on the B cells are the same as those of the antibodies produced from that cell, as these antibodies are displayed in a transmembrane form on the B cell surface. In contrast, paratopes on the TCRs are distinct from those of antibodies, and generally require recognition of a complex of peptide antigen bound to an MHC molecule. T cell and B cell epitopes and their properties will be discussed in greater detail later in this chapter.

Antigen presenting cells

As previously mentioned, T lymphocytes, unlike B lymphocytes, require antigen to first be processed into short peptides and displayed on the host cell's surface as a peptide-MHC complex, which is recognized by alpha-beta TCRs. Complete activation of naive T lymphocytes requires recognition of the appropriate MHC complex with antigen, but additional signals from costimulatory molecules and cytokines produced by the presenting cell are also required (Mueller et al., 1989; Hemmer et al., 1998). MHC class I molecules are expressed on the surface of all somatic cells, except for red blood cells, and present antigen to CD8⁺ T cells. Therefore, any host cell can present antigen to cytotoxic CD8⁺ T lymphocytes. In contrast, MHC class II molecules are expressed primarily on immune cells, in particular DCs, macrophages, and B cells, and present antigen to CD4⁺ T lymphocytes. These immune cells are considered professional APCs and are important for bridging the innate and adaptive immune responses. Thymic epithelial cells and activated T cells (in humans, but not in mice) also constitutively express MHC class II molecules, while other cell types can express MHC class II in response to interferon gamma (Piskurich et al., 1999). Because of the restricted expression of MHC class II molecules, CD4⁺ T lymphocytes mainly recognize their cognate antigen presented by a limited number of professional APCs, the most prominent being DCs (Banchereau and Steinman, 1998).

Fig. 2 Antigen presentation by APCs. Antigen presenting cells, including DCs, macrophages, and B cells, can process and present different antigens on their surface that specifically activate the distinct subsets of T cells that express antigen-specific TCRs. The specificity of this activation depends on the type of antigen, the ability of APCs to process the antigen and the MHC molecules used to display the antigen on their surface. For example, intracellular proteins are degraded in proteasome and translocated via the transport associated with antigen processing (TAP) protein into the endoplasmic reticulum (ER) lumen and loaded onto MHC class I molecules. Then they are transported to the plasma membrane to present the antigenic peptide to CD8⁺ T cells. In contrast, endocytosed extracellular proteins are processed in endosomal-lysosomal compartments and loaded onto MHC class II molecules with help of the dedicated chaperone molecule (HLA-DM in human and H2-M in mice) before the complex is transported to cell surface to activate antigen-specific CD4⁺ T cells via TCRs. However, there is also cross-presentation between these two pathways, where extracellular proteins are presented by MHC class I molecules and intracellular proteins are presented by MHC class II molecules. In addition, lipid antigens can be processed and/or presented by MHC class I-like CD1 molecules (CD1a, CD1b, CD1c, CD1d, and CD1e in human and only CD1d in mice) with the help of microsomal triglyceride-transfer protein (MTP) and different lipid-transfer proteins to activate NKT cells. Moreover, mucosal-associated invariant T cells (MAIT cells) can recognize metabolites or precursors of vitamin B (6-formylpterin, or 6-FP, a metabolite of vitamin B9, and several intermediates of the microbial biosynthesis of riboflavin, or vitamin B2) through MR1 molecules, a non-polymorphic MHC class I-like protein, presented on the surface of APCs.

In addition to the differences in constitutive expression of MHC molecules, how antigens are processed and loaded onto MHC molecules also differs. Antigens that are presented via MHC class I molecules are derived from the host cell's cytosol. Here, they are first ubiquitinated and degraded by the proteasome before being transported to the endoplasmic reticulum and directly loaded onto the MHC class I molecule (Basler et al., 2013). This pathway is also known as direct presentation and functions in all nucleated cells, serving as the mechanism for infected host cells to display antigens from intracellular viruses and bacteria to cytotoxic T lymphocytes. In addition, DCs also have the unique capacity to present exogenous antigens not derived from the cytosol via MHC class I molecules in a process called cross-presentation (Ackerman and Cresswell, 2004). For loading peptides onto MHC class II molecules, professional APCs capture exogenous proteins through endocytic vesicles and specific cell-surface receptors (Li et al., 2005). For B lymphocytes, antigen binds the surface receptor (which matches the immunoglobulin secreted by that B cell) and is internalized by receptor-mediated endocytosis. Macrophages and DCs, on the other hand, mainly internalize antigen by phagocytosis and non-specific macropinocytosis. Peptides generated from internalized antigens are loaded onto MHC class II molecules in modified endocytic compartments within APCs (Adorini et al., 1991). MHC class II molecules can also be loaded with peptides from cytosolic proteins by a process known as autophagy. This ubiquitous pathway serves to present self-cytosolic proteins to induce tolerance of self-antigen as well as to present peptides from pathogens found in the host cell cytosol (Dengjel et al., 2005). In DCs, the MHC class II processing pathway is largely regulated during the maturation process. Immature DCs continuously recycle and degrade MHC class II molecules, but upon maturation the molecules become more stable on the cell surface to allow for prolonged antigen presentation, along with increased expression of costimulatory molecules (Villadangos and Schnorrer, 2007).

Pattern recognition receptors

The human body has several barriers in place to prevent microbial pathogens from entering the body, including physical barriers like the skin and chemical barriers such as antimicrobial enzymes in saliva. If bacteria or viruses breach these barriers, host cells expressing receptors known as pattern recognition receptors (PRRs) are responsible for early detection and elimination of the pathogen. In addition to being constitutively expressed by phagocytic immune cells, like DCs, macrophages, and granulocytes, PRRs are also expressed on non-immune cells like intestinal epithelial cells and fibroblasts (Akira et al., 2006). PRRs were first hypothesized by Janeway as a connection between the innate immune response and the initiation of the adaptive immune response (Janeway, 1989). Unlike the variable antigen receptors of T and B lymphocytes, PRRs are encoded in the germline and are not modified via somatic recombination. Instead, PRRs recognize highly conserved molecular structures that are common to pathogens

called pathogen associated molecular patterns (PAMPs). Examples of PAMPs include lipopolysaccharides of gram-negative bacteria, lipoteichoic acid of gram-positive bacteria, peptidoglycan, double-stranded RNA, and flagellar proteins like flagellin, among many others. These antigens are considered essential for pathogen survival and in most cases represent unique molecular characteristics that are not found in host cells, allowing host cells to distinguish generically non-self-antigens (Janeway and Medzhitov, 2002). In addition to PAMPs, PRRs can also recognize proteins and metabolites released by apoptotic and damaged senescent host cells called damage-associated molecular patterns (DAMPs) (Bianchi, 2007).

There are several distinct classes of PRRs based on their protein domain homology, including the Toll-like receptor (TLR) family (O'Neill, 2008), the nucleotide-binding oligomerization domain-like receptors (NLR), the absent in melanoma-2 (AIM2)-like receptors (ALRs), the retinoic acid-inducible gene 1-like receptors (RLR), and the C-type lectin receptors (CLR). Each PRR family differs in the antigens that they recognize, their signal transduction pathways, and their localization within the host cell. PRRs are not only expressed on the cell membrane but are also widely distributed throughout intracellular compartments like the endoplasmic reticulum, endosome, lysosome, or within the cytoplasm. The TLRs were the first family of PRRs to be described and are classical transmembrane proteins that detect PAMPs derived from extracellular bacteria or bacteria taken into vesicular pathways by phagocytosis, or viruses (Akira and Takeda, 2004). The NLR and RLR families are soluble proteins found in the host cell cytoplasm that are important for sensing intracellular pathogens (Creagh and O'Neill, 2006). Downstream signaling pathways are induced when a PRR binds its ligand. This results in a myriad of cellular responses that act to eliminate or control the detected pathogen, some of which include production of inflammatory cytokines and other immune mediators, inducing inflammation, facilitating the elimination of dead cells, and coordinating downstream antigen-specific adaptive immune responses (Pulendran et al., 2001). However, one of the most important functions of PRRs is on DCs, where they serve to mature and activate the cells to be more effective APCs as well as to secrete cytokines and chemokines. Thus it is primarily through DCs that PRRs, especially TLRs, serve to alert the immune system to the presence of pathogens.

Factors influencing immunogenicity

There are a wide number of factors that can impact immunogenicity of antigens. However, it is ultimately determined by the interaction between the properties of the antigen and physiological state of the host. Properties of the immunogen include its foreignness, molecular size, chemical composition and heterogeneity, and the ability of the antigen to be processed and presented by an MHC molecule on the surface of an APC or altered self-cell. The host factors such as self-tolerance, the production of cytokines, and various cellular and regulatory mechanisms can impact the immunogenicity of the antigen. In addition, the quality of the immune response depends on both the amount of the antigen and the route of entry into the body as well (Morgan et al., 1999; de Visser et al., 2000; Kreuwel et al., 2002; Cook et al., 1998). Moreover, the immune system needs an adequate time of exposure to the antigen, so, for example, antigens that degrade quickly may not be able to induce strong immune responses. Also, temperature, pH, and other factors contribute to antigen-antibody interaction and strength of the immune response. Below we discuss the nature of the antigen and major *intrinsic* factors that are known to impact antigen immunogenicity.

Foreignness of the antigens

As mentioned earlier, to induce an immune response, an antigen must be recognized as non-self or foreign by the host. In general, our immune system is tolerant to molecules that are recognized as self-molecules. The degree of foreignness (or non-self) is directly proportional to the degree of immunogenicity. That is, generally the greater the phylogenetic distance between two species, the greater the structural differences, and more immunogenic the substance is (Berzofsky, 1990). In accord with this concept, some antigens are highly conserved evolutionarily across diverse species and therefore display very little immunogenicity. Based on their foreignness, antigens can be classified as: (i) *autologous antigens* (self-antigens, for which there will be no immune response because the immune system develops a tolerance to self-antigens with the exception of autoimmune disorders); (ii) *allogeneic antigens* (antigens from other members of the same species, for which there may be an immune response, for example blood transfusion antigens, organ transplants); and (iii) *heterologous or xenogeneic antigens* (antigens from different species, against which there will likely be a strong immune response).

Molecular size of the antigens

Correlation exists between the molecular size or weight of the antigen and its immunogenicity, such that the higher the molecular weight, the more likely the molecule will be immunogenic, all else being equal. The strong immunogens tend to have a molecular weight of ~100,000 daltons, whereas molecules less than 5000–10,000 daltons are usually less immunogenic with some exceptions. The number of epitopes is generally directly proportional to the size of the antigen. Larger molecules are easily phagocytosed, processed, and presented with multiple epitopes. Also, the more epitopes, the more likely that some of them will be presented by the MHC molecules of the host. Conversely, genetic non-response to certain antigens (so-called *Ir* genes) have been generally seen for small antigens with limited epitopes that may not be presented by a given MHC haplotype (Matis et al., 1982; Heber-Katz et al., 1983; Berzofsky et al., 1977; Berzofsky, 1978; Katz et al., 1982).

Chemical composition and heterogeneity of the antigens

Immunogenicity of the antigen depends upon the chemical structural complexity. Among the biological macromolecules, proteins and carbohydrates (polysaccharides) are the most investigated macromolecules. Other macromolecules, such as nucleic acid and lipids are also antigenic, but poor immunogens. Glycoproteins, nucleoproteins, lipoproteins, peptidoglycans, glycolipids, and other conjugates are also antigens. The more complex chemical structures are generally more potent immunogens than simple chemical structures. For example, homopolymers (polymers composed of a single amino acid or sugar) tend to have poorer immunogenicity regardless of their size. In contrast, copolymers of sufficient size, composed of two or more different amino acids or sugars, are usually more immunogenic than their homopolymer constituents (Cease et al., 1986). The structural stability of the antigens is essential and always needed. If the structure is unstable and degraded easily, then it will be a very poor antigen.

Protein antigens

Most proteins are probably powerful immunogens because of their high molecular weight and structural complexity; however, different proteins may differ in their immunogenicities. All four levels of protein structure (primary, secondary, tertiary and quaternary) contribute to the structural complexity of a protein and hence affect its immunogenicity (see below). Denatured primary structures of proteins are often less immunogenic than the corresponding tertiary or quaternary structure of proteins (Berzofsky, 1985).

Carbohydrate antigens

Carbohydrate antigens are polysaccharides and glycoconjugates of multiple structural configurations. Based on their origins, carbohydrate antigens are divided into microbial antigens and alloantigens (red blood cell surface antigens are alloantigens). Carbohydrates can be strong immunogens by themselves as complete-antigens, or they can be components or antigenic determinants of glycoconjugates (Ishioka et al., 1992; Jensen and Brask, 2005). Antigenic determinants of polysaccharides are usually sequential, consisting of 4–6 sugars. Microbial polysaccharides are located on the cell surface (for example, capsular polysaccharides of pneumococci) and such location is important in immune recognition. Complex lipopolysaccharide antigens (endotoxins) are found in outer membranes of a large variety of microorganisms, especially in gram-negative Enterobacteriaceae, such as *E. coli*, *Salmonella*, and *Shigella* (Mata-Haro et al., 2007; Vatanen et al., 2016; Shi et al., 2014).

Nucleic acid antigens

Nucleic acid molecules, both DNA and RNA, are poor immunogens by themselves. However, when combined with suitable protein carrier molecules they can induce humoral immune responses and produce antibody with high specificity. Microbial pathogens can be recognized by multiple PRRs, including TLRs. Nucleic acids can be recognized by TLRs and induce strong immune responses (TLR3 for dsRNA, TLR7 for ssRNA, and TLR9 for dsDNA) (Kim et al., 1998).

Lipid antigens

Lipid molecules are not soluble in water and poorly immunogenic by themselves. However, lipids are usually associated with cell membranes or lipid-binding proteins in the body. Lipids can be immunogenic when they are presented by an MHC-like molecule, CD1, to which lipid binds, on the surface of APCs and stimulate NKT cells (Prigozy et al., 2001). To date, several lipid antigens of microbial and self origin have been identified (Shamshiev et al., 1999; An et al., 2014; Brennan et al., 2011; Kawano et al., 1997; Kinjo et al., 2005; Mattner et al., 2005; Sriram et al., 2005).

Haptens

Haptens are an additional structural category of antigens that can have any of the above molecular structural compositions, peptide, carbohydrate, nucleic acid or lipid, or even small organic molecules. What makes them haptens is that they are low molecular weight compounds that are capable of specifically binding to an antibody but cannot themselves initiate antibody production; in other words, they are antigenic but not immunogenic. Haptens were first described in the 1930s by Karl Landsteiner, who conducted numerous animal studies to characterize their nature (Landsteiner and Van der Scheer, 1934; Landsteiner and Jacobs, 1935). Much of what was first learned about how antibodies bind to antigen and the variability of antibodies is based upon initial studies of antibodies binding to haptens (Pauling et al., 1941; Eisen and Siskind, 1964). Haptens are unique from antigens in that to be immunogenic they must be covalently linked to a carrier molecule, like a protein. It is only when haptens are conjugated to a carrier molecule that they can directly activate B lymphocytes by cross-linking of multiple surface B cell receptors (Boak et al., 1971; Abbas et al., 1985). Furthermore, it is unlikely that haptens alone are capable of binding to MHC molecules or the T cell receptor directly. The carrier protein provides a source of epitopes to induce CD4⁺ T cell help. Instead, the hapten-carrier conjugate must be linked so the components get into the same DC, which can process and present helper epitopes from the carrier to helper T cells, and the hapten can be presented to B cells that are proximal to the same DC to receive the help. There are also T cells that can recognize a complex epitope consisting of a combination of MHC molecule loaded with a carrier peptide to which the hapten is attached. For example, T cells that see glycopeptides with a sugar moiety (Huang et al., 1996). The peptide conjugate can act to anchor the hapten within the MHC binding groove during loading onto the MHC molecule (Ortmann et al., 1992; Martin and Weltzien, 1994). A similar phenomenon has been described for CD8 T cells instead of B cells, in that the class II MHC-restricted helper epitope needs to be physically associated with or covalently linked to the class I MHC-restricted CTL epitope for immunogenicity (Shirai et al., 1994).

Unintended coupling of a hapten to peptide is responsible for numerous pathologies, including the allergic reaction many people experience to penicillin and other beta-lactam antibiotics. This occurs when the drug is metabolized into prohaptens that can bind to endogenous proteins and elicit deleterious immune responses directed toward conjugated self-proteins (Garratty, 2009; Chung et al., 2016). Hapten-specific T cells are also responsible for inducing skin pathology in contact hypersensitivity reactions to the toxin urushiol in poison ivy, which reacts with host proteins to form a coupled hapten. Many other molecules including metal ions like nickel, industrial chemicals, and even cosmetic additives like fragrance or lanolin, have been shown to illicit adverse immune responses due to hapten-coupling (Dumycz et al., 2019). The mechanisms by which haptens interact with endogenous proteins to induce pathology are still currently being characterized. Most haptens are electrophilic molecules that covalently bind to nucleophilic residues on endogenous proteins to create a new antigenic epitope (Chipinda et al., 2011). It is still unknown, however, if certain self-proteins are more prone to interact with haptens or prohaptens than other proteins. It has also been suggested more recently that haptens could potentially bypass the classic MHC-TCR pathway to directly stimulate T lymphocytes (Pichler, 2005). This new pathway, called the pharmacological interaction with immune receptors concept (or p-i model), suggests that certain metabolites from drugs could bind specifically to antigen receptors directly, acting much like a super antigen. This model proposes that drug metabolites may not be able to activate naïve T lymphocytes directly, but if a hapten were to bind to primed T lymphocytes, which have a lower antigen threshold, stimulation could occur (Pichler et al., 2006).

Ability of the antigen to be processed and presented by APCs

The development of both humoral and cellular immune responses requires interaction of T cells with antigen that has been processed into small fragments within cells, loaded onto an MHC molecule and presented on the surface by APCs (Germain and Margulies, 1993; Crotty, 2011). Recognition of antigen involves close contact binding of the TCR on the surface of T cells and the antigen-fragment-MHC expressed on the surface of APCs, as described earlier in this chapter. Antigens that cannot be phagocytosed, processed, and presented with MHC molecules are poor immunogens. Large, insoluble macromolecules are usually more immunogenic compared to small, soluble molecules because they not only potentially contain multiple epitopes but also are phagocytosed more readily and processed easily to induce immune responses (Berzofsky, 1985; Cease et al., 1986).

Based on their origin, antigens can also be classified as *exogenous* or *endogenous* antigens, where the exogenous antigens enter the cell from the outside (through endocytosis) and endogenous antigens are generated inside the cell as part of cell metabolism or pathogenic infection within the cell. Exogenous antigens phagocytosed and endosomally processed by APCs and presented on MHC class II molecules activate CD4⁺ helper T cells to activate APCs and secrete cytokines to activate B cells, cytotoxic T cells, and macrophages (Berzofsky et al., 1986). In contrast, endogenous antigens are processed in the cytosol and transported to the endoplasmic reticulum where they are loaded onto MHC class I molecules to activate CD8⁺ cytotoxic T cells, which release toxins like granzymes and perforin that induce apoptosis or lysis of the infected cells (Seder and Ahmed, 2003).

To improve immunogenicity, Immunologists have employed what Charlie Janeway (Janeway, 1989) called the immunologists' "dirty little secret," namely adjuvants, as described in the next section.

Adjuvants

Adjuvants are substances that act to enhance the immune response against an antigen and are used to augment and prolong the immunogenicity of vaccine formulations. This phenomenon was first described by a French veterinarian working on the diphtheria and tetanus vaccine in the 1920s. Gaston Ramon observed that vaccinated horses developed a stronger immune response if they also experienced inflammation at the site of injection. He went on to inject substances like starch and breadcrumbs to induce sterile abscesses where he also injected inactivated toxin, which increased the antigen-specific antibodies in serum (Di Pasquale et al., 2015). The molecular mechanisms by which adjuvants work are still not fully understood and most adjuvants use more than one mechanism of action to enhance the immunogenicity of the substance they are administered with. The formation of an injection site depot was the first mechanism of action described for adjuvants. The depot effect involves antigen trapping at the site of injection and ensures slow release and prolonged stimulation of the immune system. The depot effect is thought to be one of the mechanisms of action of many alum-based adjuvants, which are the most widely used adjuvants today, as antigen has been detected for up to 3 weeks in alumina gel granulomas (Awate et al., 2013). After PRRs were first described in the 1990s (Janeway, 1989), the connection between innate cell signaling and the downstream activation of adaptive immune cells became apparent. Today, most adjuvants use bacteria, bacterial or viral components, or mimics such as TLR ligands to enhance immunogenicity through PRR signaling, though the exact molecular mechanisms are still being elucidated. Potential mechanisms of action include regulating cytokines and chemokines, increasing cellular recruitment at the site of injection, enhancing antigen uptake by APCs and their migration to draining lymph nodes, or by activating inflammasomes (Coffman et al., 2010; Pulendran et al., 2021).

Despite nearly a century of research on adjuvants, very few have been approved for use in humans. The FDA says it does not approve adjuvants on their own, but only as part of a specific vaccine formulation. In 1932, aluminum became the first adjuvant to be used in a human vaccine and for 70 years was the only adjuvant product in vaccines licensed for human use. To date there have been only five other adjuvant systems approved for use in the United States. In the 1990s, an oil-in-water emulsion adjuvant called MF59 was introduced as part of a trivalent inactivated vaccine against seasonal influenza. Complete Freund's adjuvant, a water-in-oil emulsion that includes killed mycobacteria is widely used in animal studies but has not been approved for humans because of

injection-site granulomas. It has both the depot effect of trapping the aqueous phase in oil, and the TLR ligands of the mycobacteria. More recently, the adjuvants AS01 and AS04 have been included in vaccine formulations for shingles, malaria, hepatitis B, and human papilloma virus. The adjuvant cytosine phosphoguanosine (CpG) 1018 was approved as part of a hepatitis B vaccine, as CpG oligonucleotides mimic bacterial DNA which is richer in these sequences than mammalian DNA, and the CpG oligonucleotides have been shown to bind to TLR9. Most of the approved adjuvants work as part of a system, with more than one adjuvant substance included in the formulation. For example, AS01 is a liposome-based adjuvant that contains two different immunostimulants: monophosphoryl lipid A (a ligand of TLR4, representing a component of bacterial lipopolysaccharide (LPS) that itself may be too toxic), and QS-21, a natural compound from the Chilean soapbark tree that provides the depot effect and helps transport molecules across cell membranes (Didierlaurent et al., 2014). Also, QS21 in nanoparticles called ISCOMs was found to permit large soluble proteins to enter the cross-presentation pathway and stimulate CD8+ T cells (Takahashi et al., 1990). There have been numerous other formulations used experimentally or tested in clinical trials, but most have been deemed unsafe due to severe side effects or tolerability concerns. For instance, in the early 2000s an intranasal HIV gp120 vaccine using the adjuvant LTK63, a mutant of *Escherichia coli* labile toxin that is an effective mucosal adjuvant (Belyakov et al., 2000, 2001), was pulled from use when several study participants in the trial developed transient facial nerve paralysis (Bell's palsy) (Lewis et al., 2009). Another widely used adjuvant is poly I:C, a double stranded RNA that mimics double-stranded RNA viruses and binds TLR3. This is the only TLR ligand that signals through TRIF, rather than MyD88, so it has been found to be synergistic with some others like TLR 9 and TLR2/6 ligands that signal through MyD88 (Zhu et al., 2008; Sui et al., 2011). Further, targeting TLRs and NLRs simultaneously has also been found to be synergistic in improving an anti-tumor immune response (Garaude et al., 2012; Berzofsky, 2012).

Adaptive immune cell epitopes

For adaptive immune responses, the antigenic epitopes must be recognized by the receptors of T cells or B cells. Thus, it is important to be able to characterize those epitopes and map them within the larger structure of an antigen molecule, as discussed below.

Properties of B-cell epitopes

Antibodies made by B lymphocytes can recognize all classes of antigens, such as proteins, lipids, nucleic acids, and carbohydrates, as well as haptens, as discussed earlier in this chapter. Much early work was done on the structure of carbohydrate epitopes (Kabat, 1978, 1960), including work that helped map the size and shape of the antibody combining site by defining the limits of the carbohydrate size that could fit (Kabat, 1960). However, most structural work in recent years has focused on protein antigens.

Globular proteins have at least 4 levels of structure: primary, secondary, tertiary and quaternary, and many are also glycosylated or otherwise post-translationally modified, creating additional epitopes. Primary structure is just the amino acid sequence. Although primary structure is critical for antibody recognition and can determine specificity, it rarely acts alone as such sequences usually take on some secondary or higher structure. Secondary structure is the local folding of the amino acid sequence, in the form of alpha helices, beta sheets, and many less defined structures. An antibody will certainly distinguish different secondary structures of a given amino acid sequence. As proteins breathe, that is expand, contract and flex in solution, some conformations may bind to an antibody with higher affinity than another conformations (Sachs et al., 1972; Furie et al., 1975). Conversely, the antibody thus can shift this conformational equilibrium toward one of those conformations to which it has higher affinity (Crumpton, 1974; Lando et al., 1982; Dean and Schechter, 1979). These epitopes can therefore be called "conformational epitopes" even though they exist as a continuous amino acid sequence because the antibody recognition depends on the protein conformation.

Tertiary structure, the three-dimensional folding of the protein, can create another more complex type of conformational epitope, by bringing in close proximity regions of amino acid sequence that are far apart in the linear sequence. When such regions fall within the radius of recognition of an antibody binding site, the antibody recognition can depend on a combination of sequence segments brought together by the folding that are juxtaposed only in the tertiary structure, and thus completely dependent on such tertiary structure. We have called these "assembled topographic epitopes" because they are assembled from disparate portions of the amino acid sequence and brought together by its folding (Benjamin et al., 1984). They are also sometimes just called "discontinuous" or conformational epitopes, but these should be distinguished from conformational epitopes that depend only on secondary structure, as the latter can occur even in short peptides that oscillate among different secondary structures (Benjamin et al., 1984; Getzoff et al., 1987, 1988; Van Regenmortel, 1987).

When we look at the surface of most globular proteins and examine the radius of an antibody combining site that could sit on the surface, we usually find that the antibody would very likely span segments of the amino acid sequence that come from different regions of the linear sequence (Barlow et al., 1986), in other words, assembled topographic epitopes (Berzofsky, 1985). Thus, in fact, most epitopes of intact globular proteins may be of this assembled topographic type.

Quaternary structure is the assembly of multiple subunits of a multi-subunit protein. These can be heterodimers/trimers, like the alpha-beta-gamma subunits of the IL-2 receptor, or they can be homodimers, trimers or tetramers. One example is hemoglobin, which forms a tetramer of four chains that can each bind oxygen. Antibodies that favor the oxygen-binding conformation of one subunit can shift the equilibrium of the others to promote oxygen binding by all 4 subunits (Dean and Schechter, 1979). However, these antibodies generally bind one subunit at a time. It is relatively rare to find antibodies that require quaternary structure because the epitope bridges between or spans across more than one subunit. That lack of examples, however, may relate to the relative lack of experiments to detect such quaternary structural epitopes.

Properties of T cell epitopes

In contrast to antibody epitopes, T cell epitopes, at least for conventional CD4⁺ and CD8⁺ alpha-beta TCR T cells, are short peptides presented by class II or class I MHC molecules, respectively (Rötzschke et al., 1990; Germain and Margulies, 1993; Davenport et al., 1997). Therefore, there is no issue with conformational epitopes or assembled topographic epitopes. Only the primary structure needs to be considered for the most part.

In the case of CD8⁺ T cell recognition of peptides presented by class I MHC molecules, like HLA-A, B and C in humans and H-2K, H-2L, and H-2D in mice, the peptides must fit in the groove of the MHC molecule, usually with the N and C termini fitting into pockets at either end of the groove, and anchor residues fitting in pockets in between. The outside pockets binding the terminal amino acids constrict the length of the peptide, generally between 8 and 11 residues, with the majority being 9 or 10 residues long. The other pockets define what type of anchor amino acid side chains can fit in a particular MHC molecule, and thus determine which peptides can be presented by that MHC molecule. These primary anchor residues, as well as secondary anchors and other positions at which side chains can interfere, define a sequence “motif” that is predictive of peptides that can bind to a particular class I MHC molecule. Such motifs were first discovered by Rammensee and colleagues for HLA-A2-binding peptides (Rötzschke et al., 1990; Falk et al., 1990) and by Maryanski, Romero and Corradin for H-2Kd binding peptides (Maryanski et al., 1990; Romero et al., 1991). Rammensee’s group sequenced peptides eluted from MHC molecules, and since in class I molecules they were all aligned starting with the N-terminal residue fitting in a pocket, they could see a pattern that certain positions were highly variable, whereas other positions were conserved among peptides binding to a particular HLA molecule. For example, the first one extensively studied was HLA-A2, the most common class I HLA molecule in humans at least of European descent. They found that the second position and C-terminal position were conserved and virtually always had a hydrophobic aliphatic side chain such as Leucine, Valine, or Isoleucine, or sometimes Methionine. Such motifs were later refined by Sette and coworkers (Ruppert et al., 1993), who examined the effects of different residues at other positions. Such motifs have become the basis of many predictive algorithms for locating CD8⁺ T cell epitopes (see below).

For class II MHC molecules, presenting peptides to CD4⁺ T cells, the situation was more complex because the ends of the peptide could stick out from the ends of the groove, so the peptides were not all aligned from the same starting point. That made it more difficult to identify motifs. Nevertheless, motifs for different class II MHC molecules, such as HLA-DR, DQ and DP in humans and I-A and I-E in mice, have been characterized (Rammensee et al., 1995a). These allow predictions, but perhaps not yet as reliably as for class I MHC molecules.

We also found that non-anchor residues, if too bulky, could interfere with binding by steric hindrance and thus reduce affinity even when appropriate anchors were present (Boehncke et al., 1993). In that case, replacing such a bulky residue with a small alanine (with just a methyl group as side chain) removed the steric hindrance and increased the binding affinity. We conclude that all the residues in the amino acid sequence need to be considered, not just the anchors. Further, based on these observations, we formulated the concept of “epitope enhancement” in which we can modify the amino acid sequence of the epitope to increase affinity for the MHC molecule and thus increase immunogenicity (Berzofsky, 1995; Berzofsky et al., 2001). Sette et al. had shown a strong relationship between peptide affinity for MHC molecules and immunogenicity of the epitope (Sette et al., 1994). The idea is that if certain amino acid residues in the peptide interact exclusively with the MHC molecule and others exclusively with the TCR, then one could modify the former ones to improve affinity for the MHC molecule through either anchor improvements or replacement of interfering residues, without affecting what the TCR could see when it looks down on the peptide-MHC complex and sees the MHC molecules with certain peptide residues exposed out of the groove. Of course, this is overly simplistic, as some residues might interact with both MHC and TCR, and even the residues that interact exclusively with the MHC molecule could still affect the conformation of the part of the peptide exposed from the groove, and thus affect the fit into the TCR. Since the goal is to make a more immunogenic peptide as a vaccine that still elicits T cells that “see” the natural pathogen or cancer antigen, which is not altered, the epitope enhancement process must not alter the specificity of the T cells elicited. In practice, many epitope-enhanced peptides can elicit T cells that react with the natural unmodified sequence, but some do not and have to be screened out empirically by immunization studies. Also, some T cells elicited may crossreact with the wild type sequence and some may not, and the latter would be wasted. Despite all these caveats, the method has been used successfully to improve epitopes from hepatitis C virus, HIV, and other viruses, and cancer antigens (Sarobe et al., 1998; Ahlers et al., 1997; Oh et al., 2004; Huang et al., 2013). At least one of these, from the prostate cancer antigen TARP, has been used successfully in phase I clinical trials and shown evidence of clinical benefit (Wood et al., 2016).

This concept of epitope enhancement has been extended by Kosmatopoulos et al (Tourdot et al., 2000; Gross et al., 2004) in a very interesting idea: T cells specific for the most dominant high affinity cancer antigens (see immunodominance below), may have been tolerized by thymic deletional tolerance or other tolerance mechanisms as self, and thus not be induced by the corresponding cancer antigen in vaccines or in the tumor. However, lower affinity cancer peptides, defining subdominant epitopes, may not have induced tolerance but may be of too weak affinity to elicit a protective response either. The idea is that these weaker epitopes could be strengthened by epitope enhancement to gain higher affinity and thus greater immunogenicity, to be used in vaccines to expand non-tolerized T cells that could then target the cancer. They demonstrated the ability to do so in mouse cancer models.

There are also a set of alpha-beta TCR T cells that recognize non-peptide antigens presented by non-classical MHC like molecules, often using semi-invariant TCRs, as well as gamma-delta TCRs (Godfrey et al., 2015). For example, type I or invariant NKT cells (distinct from NK cells that lack a TCR) recognize lipid antigens presented by the class IB MHC molecule CD1d (Kronenberg and Gapin, 2002; Brutkiewicz et al., 2003; Godfrey et al., 2004; Bendelac et al., 2007; Terabe and Berzofsky, 2008,

2016; Brennan et al., 2013). These provide the T cell immune system a way to detect lipid and glycolipid antigens, which would be invisible to classical peptide-specific T cells. CD1d is the only CD1 molecule in mice, but in humans there are others, CD1a, b and c, which each present different lipids and glycolipids to T cells, for example from mycobacteria (Vincent et al., 2003; Cohen et al., 2009). Another set of semi-invariant TCR T cells that see non-peptide antigens are the Mucosal-Associated Invariant T (MAIT) cells, that see primarily riboflavin precursors, largely from bacteria, presented by the MR1 molecule (Kjer-Nielsen et al., 2012; Koay et al., 2019). Thus, although conventional T cells focus on protein antigens, the adaptive cellular immune system has evolved other T cells, perhaps even more primitive, that allow detection of other types of structures. Another case in point is the ability of even conventional T cells to detect carbohydrate moieties as haptens on peptide epitopes, which thus alter the specificity (Ishioka et al., 1992; Huang et al., 1996). The T cells that see the glycosylated peptide do not crossreact with the non-glycosylated peptide of the same amino acid sequence presented by the same MHC molecule.

Epitope mapping

B cell epitope mapping

The conformational nature of most protein B cell (antibody) epitopes makes epitope mapping difficult. One widespread method is to measure antibody binding to a series of overlapping synthetic peptides covering the whole protein sequence. The problem is that this is limited to detecting epitopes that exist in relatively short peptides, and in the conformation that the peptides can easily adapt when separated from the native protein, and when bound to various media like a microtiter plate. Assembled topographic epitopes would be completely missed by this method.

A second method is to make point mutations in different locations within the intact folded protein to see which ones interfere with antibody binding (this assumes one is dealing with a monoclonal, monospecific antibody). Originally this approach was carried out using natural variants such as myoglobins or lysozymes from different species with known differences in amino acid sequence (Berzofsky et al., 1982; Benjamin et al., 1984). When recombinant methods such as site-directed mutagenesis became available to make point mutations, that became a more widely applicable approach, and this has now become greatly facilitated by use of CRISPR/Cas9 technology (Jinek et al., 2012; Hsu et al., 2014; Ran et al., 2013).

A third method is to carry out competition studies with a monoclonal antibody whose epitope has already been mapped (Streicher et al., 1986). The presumption is that an antibody that competes must be binding in the same region of the protein as the known antibody to mediate steric hindrance. That may define epitopes that are overlapping, but not necessarily identical. Similarly, one can examine antibodies that compete for antibodies known to neutralize a virus. Of course, there are exceptions when allosteric effects on conformation can allow one antibody to change the conformation of the protein antigen in a way that affects binding of a second antibody at a distance. This same caveat also applies to the point mutation method, so one has to have corroborative data to confirm the interpretation.

T cell epitope mapping

T cell epitopes are much easier to map with overlapping peptides as they depend almost completely on primary structure, that is, amino acid sequence. For CD8⁺ T cells, since class I MHC molecules bind peptides in the 8-11-mer range, if the peptides overlap by 10 residues, then any epitope up to 11 residues long would be present in at least one of the overlapping peptides. For peptides presented by class II MHC molecules to CD4⁺ T cells, one has to use longer peptides, but still an overlap of about 15 residues should capture most epitopes. This method can be tedious and labor-intensive, but newer methods to synthesize large numbers of peptides and use array techniques has facilitated this brute force approach.

When it is not feasible to do such empirical mapping, one can use methods developed to predict the location of T cell epitopes based on structural features. An early approach was based on the observation that many T cell epitopes had hydrophobic sides (Stille et al., 1987) or hydrophobic periodicity consistent with that of an alpha helix, before the structure of peptides binding to MHC molecules was determined by X-ray crystallography (DeLisi and Berzofsky, 1985; Margalit et al., 1987; Cornette et al., 1995). When it became obvious that the peptides were not bound in a helical conformation, it was then found that hydrophobic periodicity like an alpha helix was characteristic of the spacing of the anchor residues binding to pockets in the MHC groove, which were often hydrophobic, and thus could be explained by this pocket spacing (Cornette et al., 1995). Anchors were often at positions 2 and 9 (like 2 turns of an alpha helix with 3.6 residues per turn) or at 2 and 5 or 5 and 9, about one turn of a helix apart. Such general methods were supplanted by MHC-motif specific methods when those motifs were identified, so one could look for peptides with the right spacing between residues that served as anchors in a particular MHC molecule, such as the hydrophobic anchors at position 2 and 9 for HLA-A2 (Rammensee et al., 1995b). More refined matrix approaches looked at the probability of a particular amino acid at any position in a peptide binding to HLA-A2, for example (Ruppert et al., 1993; Rammensee et al., 1999). A number of such algorithms are available on the internet. Although motifs for many class II molecules are not as well defined yet, algorithms for these are also available. The reliability of such algorithms is largely dependent on the amount of data (number of known epitopes examined) used to create the algorithm, and so should be more reliable for HLA-A*0201 than for some rare HLA alleles. Other machine learning or artificial intelligence methods have been used to make predictions of T cell epitopes, such as threading approaches and neural networks (Altuvia et al., 1995; Brusica et al., 1994). Further improvements have been made by mass spectrometry analysis of peptides bound to MHC molecules (Hunt et al., 1992; Abelin et al., 2017, 2019). Predictive algorithms

have been greatly refined over the years so that they are extremely reliable (Meister et al., 1995; DeGroot et al., 1997; Gulukota et al., 1997; Zhang et al., 1998, 2007; Lin et al., 2008; De Groot et al., 2020; Peters et al., 2020). Thus, at least for common MHC molecules for which much data are available, predictive algorithms may be able to replace empirical assays for epitope mapping, although the only method to capture all epitopes is by experimental testing of T cell responses to all possible peptides.

Immunodominance

It has been observed that T cell epitopes are not all created equal. Some elicit much stronger responses than others (Vitiello et al., 1996). When one or two dominate the whole response, these are called immunodominant epitopes, and the weaker ones are called subdominant. In fact, these are not just quantitative differences, because removing a dominant epitope can sometimes allow a stronger response to what had been subdominant epitopes, that now move up the hierarchy (Gross et al., 2004; Grossmann et al., 2001; Slifka et al., 2003). This finding suggests some kind of competition, possibly for growth factors, or just for antigen-presenting cells.

Several mechanisms have been proposed for immunodominance. One involves affinity of the peptide for the MHC molecules of the host. It has been shown that higher affinity peptides are more immunogenic and can induce stronger responses (Sette et al., 1994; Alexander et al., 1993). There is also the affinity of the TCR for the peptide-MHC complex, which can affect the response. More generally, the available TCR repertoire may play a big role in immunodominance. If there are more T cells present with a particular TCR for a particular epitope even before exposure to the pathogen, cancer or vaccine, then that epitope will have a greater chance of dominating the response. That greater prevalence could be due to intrinsic genetic factors, like the availability of V, D and J regions or their accessibility for VDJ recombination, or to extrinsic factors, like the history of the host's prior exposure to crossreactive epitopes that could have expanded that repertoire. We found, for example, that when we compared different congenic strains of mice sharing the same MHC but different genetic backgrounds, the response to the same peptide epitope showed different degrees of immunodominance depending on non-MHC genes in that strain (Dzutsev et al., 2007). One key difference in those strains that share the same MHC is the gene cluster of TCR genes, which is the most likely suspect. Whichever set of T cells gets a head start in the response, perhaps by having higher avidity for the peptide-MHC complex, a larger repertoire or a previously expanded one, may out-compete the other epitopes and become dominant.

Immunodominance has translational relevance, because dominant epitopes are often the ones to which T cells are tolerized, or which may select for escape mutations because they exert the most selective pressure. Therefore, targeting non-dominant epitopes may be an important strategy in vaccine development (Slifka et al., 2003), perhaps combined with epitope enhancement as discussed above, to avoid this problem.

Conclusions

In summary, antigens are any type of molecule that can be recognized by specific receptors of the adaptive immune system on T cells and B cells. They can consist of proteins or peptide fragments of proteins, carbohydrates, nucleic acids (DNA or RNA), lipids, or even haptens, which are molecules too small to induce an immune response by themselves but can be recognized by antibodies once those are made. To induce antibodies against haptens, one needs to couple them to a larger immunogenic molecule, called a carrier, to provide a source of T cell help. Unlike B cells or antibodies, T cells don't recognize free antigens in solution, but only peptide fragments of protein antigens presented by an MHC molecule on an APC, such as a DCs. Thus, individuals with different MHC haplotypes (HLA haplotypes in humans) will have different repertoires of antigens they can recognize. In general, CD4⁺ T cells recognize antigens presented by class II MHC molecules such as HLA-DR, DQ or DP in humans or I-A or I-E in the mouse. These generally result from endosomal uptake of antigens from outside the APC. On the other hand, CD8⁺ T cells generally recognize peptide antigens presented by class I MHC molecules such as HLA-A, B or C in humans or H-2K, D, or L in mice. These are most often derived from proteasomal processing of antigens made in the cytosol, such as viral antigens in an infected cells, and are then loaded onto the class I MHC molecules to be carried to the cell surface. Some peptides can be cross-presented to CD8⁺ T cells even from exogenous antigens, as described above.

To be immunogenic, an antigen must not only be recognizable by the immune system (antigenic), generally as foreign (so not subject to self tolerance), but also be able to activate the immune system., which defines them as immunogenic. That often requires triggering PRRs such as TLRs on APCs that activate these APCs and thus alert the immune system. Most pathogens do this naturally, by expressing their own PAMPs such as TLR ligands. However, for individual soluble protein antigens, so called subunit vaccines, one needs to add such signals to the vaccine, in the form of adjuvants. This adjuvant trick is what Charlie Janeway called "the immunologist's dirty little secret" and adjuvants have made possible vaccines composed of single recombinant proteins. Thus, understanding the nature of antigens and how to make them immunogenic has greatly improved our ability to make a wide range of vaccines that have saved millions of lives from infectious diseases, and may soon be able to treat or even prevent cancers as well.

Introduction

Antigen presentation is a process of displaying parts of antigenic fragments—epitopes—to the immune cells bearing corresponding antigen receptors. Antigen can be presented by any nucleated cell of the organism, but there is a specific subset of cells called professional antigen presenting cells (pAPCs), e.g., B cells, macrophages, Langerhans cells, microglial cells or thymic cortical epithelial cells. Antigen presentation is essential for the development of adaptive immune response. For example, germinal center B cells recruit help from follicular helper T cells (T_{fh} cells) to produce high affinity antigen-specific antibodies. At the same time, macrophages which display antigen are activated by helper T cell cytokines thus making antigen presentation important for the innate immunity. The latter is particularly important for the clearance of pathogens residing and replicating inside macrophages, e.g., *Leishmania* and mycobacteria. Major histocompatibility complex (MHC) is a molecular machinery that makes antigen presentation possible. Human MHC molecules were named the human leukocyte antigens (HLA) system. Basic principle of its functioning can be defined as ‘capturing’ of self and foreign antigenic components inside the cell with the consequent transport of these components to the cell surface. Here, the antigen-MHC complex can be recognized by T cells which inspect cells of the organism for the presence of foreign matter or abnormal self proteins. T cells do not recognize native antigens like immunoglobulins do, and they need antigen to be displayed by MHC complexes. Every nucleated cell expresses about 10⁵ major histocompatibility complex class I molecules (MHC class I) in complex with endogenous (cytosolic) antigen peptides which can be recognized by specific CD8⁺ (cytotoxic) T cells. However, the level of expression may differ among different cell types. Lymphocytes exert the highest class I expression while muscle and liver cells are characterized by low expression level (a fact explaining relatively low frequency of liver graft rejection). pAPCs constitutively express MHC class II molecules in complex with exogenous (extracellular) antigen peptides which are recognized by specific CD4⁺ T cells. MHC class I and II display peptide antigens. Native antigenic peptides are prepared before they fit MHC molecules in a pathway referred to as antigen processing. There are also non-classical MHC molecules, such as CD1d, that can bind lipid antigens. MHC expression can be upregulated by interferons (α and β interferons for class I and γ interferon for class I and II) and TNF facilitating immune response against pathogens but also predisposing for the autoreactive T cells activation. IFN- γ action is associated with MHC class II transactivator (CIITA) which promotes MHC class II genes. Loss of CIITA leads to severe immunodeficiency development. Thus, abnormal MHC regulation has strong consequences for the organism health (Abbas et al., 2019).

Basic structure of MHC molecules and MHC-peptide complexes

Both HLA class I and class II molecules are composed of two polypeptide chains that form a structure suitable to hold short antigenic peptides. Class I molecular complex is a heterodimer composed of immunoglobulin superfamily α -chain (45 kDa) noncovalently associated with β 2-microglobulin (12 kDa). α -Chain is presented by one of the three types: A, B, C and is organized into three extracellular domains (α 1, α 2 and α 3) and a cytoplasmic anchor that spans the membrane. MHC class II is constituted by two noncovalently associated nonidentical transmembrane glycoprotein chains α (33 kDa) and β (28 kDa): DP, DQ, DR (Fig. 1). Each chain possesses extracellular α 1 and α 2 domains or β 1 and β 2 domains structurally similar to those of MHC class I domains. Polypeptide chains of HLA complexes form peptide-binding grooves, or peptide-binding clefts, on the top surface of the molecule that fit peptides 8–11 amino acids in length in class I and 13–25 amino acids in length in class II molecules. The structure of grooves determines which peptides will bind here. These peptides are generated during antigen processing. Peptides are contained in grooves via their conserved motifs which can be different for different HLA molecules. Peptide-binding groove is closed at both ends

Fig. 1 Structure of MHC molecules.

in class I molecules and is open at both ends in class II molecules and that is a major differences in structure between two MHC classes (Abbas et al., 2019; Male et al., 2020).

Most of the peptides bound to MHC class I molecules are monomers nine amino acids in length that form a 'sandwich' together with α -domains of the MHC molecule. Peptide anchor residues are contained at both ends of peptide; similar anchor residues may be present in different peptides in the same positions in the amino and carboxy termini of the sequence. Given the number of expressed MHC molecules on the surface, this means that any individual cell can simultaneously present a wide range of different peptides to CD8 + T cells. Different peptides are anchored by the same amino acids through hydrogen bonds and ionic interactions. Peptides longer than nine amino acids are accommodated in the peptide-binding groove by making a twist in the peptide backbone, or, in some cases, by letting the residues of the carboxy terminus to hang out of the groove (Abbas et al., 2019; Male et al., 2020).

Peptides bound to MHC class II molecules are longer than the peptides that bind to class I molecules and contain internal binding motifs than distributed along the peptide backbone rather than at the ends of the peptides, which extend beyond the groove edges. It is interesting that number and distance between peptides that interact with MHC binding pockets is conserved: four anchor residues (R) are separated in this manner: Y-R1-X-X-R4-X-R6-X-X-R9-Y, where Y designates up to six residues at the amino and carboxy termini and X designates amino acids between anchors. Properties of anchor residues, such as hydrophobicity or charge, also remain conserved in the corresponding positions. Additional promiscuity of these peptides is often provided by proline residues contributing to structural flexibility. A notable feature of peptide binding both in MHC class I and II is that the binding is sufficiently strong and stable to prevent dynamic peptide exchange at the cell surface. Moreover, peptide binding stabilizes MHC molecules preventing them from dissociation; this also allows purification and analysis of peptide-MHC complexes for research purposes (Abbas et al., 2019; Male et al., 2020).

MHC genetics

MHC molecules are encoded by genes located at the HLA region on chromosome 6 in humans and on murine chromosome 17. However, human β 2-microglobulin is encoded by a non-HLA gene of chromosome 15. Historically these regions were discovered during the search for the graft rejection mechanisms, hence the name 'histocompatibility'. Genes located at the MHC class I and class II regions also code for different molecules that perform different functions. There is also MHC class III gene region which products include complement components and immunoregulatory molecules that are not always directly associated with antigen processing and presentation during the immune responses (Abbas et al., 2019; Male et al., 2020).

Class I genetic loci include genes encoding antigen-binding *HLA-A*, *HLA-B*, and *HLA-C* molecules. Class II genes *DPA*, *DPB*, *DQA*, *DQB*, *DRA*, *DRB* encode corresponding subunits of antigen-binding molecules (Fig. 2). This class II molecules basically have the same function thus MHC gene region is said to be polygenic: multiple genes encode products with only slightly different structures. Impressive number of alleles in these loci constitutes the basis of HLA polymorphism, or allelic variation within the species. Exception is the *DRA* which is monomorphic (Matern et al., 2020). Alleles are designated by the number in humans, e.g., *HLA-A1*, *HLA-A2*, *HLA-A3*, ..., or *HLA-DR1*, *HLA-DR2*, etc. As of December 2020, number of HLA class I and class II identified alleles has

Fig. 2 Simplified map of HLA region on chromosome 6. Classical class I and class II genes are shown in dark blue and green. Nonclassical class I genes and class II genes involved in antigen loading are shown in light blue and green correspondingly.

reached 20,597 and 7723, correspondingly, making it one of the most polymorphic genetic complexes in humans. Most important polymorphisms affect DNA regions that encode protein sequences of the antigen-binding groove. Moreover, multiple genes for α and β chains are present in some individuals encoding different protein isoforms. Also, any DR α -chain can be paired with any DR β -chain. Altogether, MHC diversity is exhibited at both the individual and species level. Genetic polymorphism and versatile α - β chain associations allow a high diversity of antigens that can be presented on individual level and also ensures population resistance to a range of infective agents rather than equal susceptibility to a number of pathogens. At the same time, this HLA diversity makes graft donor-recipient matching quite challenging and some alleles predispose individuals to autoimmune diseases (Murphy and Weaver, 2016; Punt et al., 2018; Rich et al., 2018).

Any individual expresses a small part of MHC repertoire: up to 6 class I molecules and up to 12 class II molecules which are able to bind a bind an enormous array of different peptides. Vice versa, any exact peptide can be presented by several different MHC molecules in contrast to highly specific antigen-antibody or antigen-TCR interactions. However, T cells distinguish between similar peptides in complex with different MHC molecules, that is the essence of MHC restriction.

Allele set in each individual is called haplotype. Some haplotypes are more frequent in population than others which somewhat contradicts expected gene distribution; this phenomenon is called linkage disequilibrium. It reflects human migration history and natural selection process which outsorts allele sets that are less useful in terms of infection resistance. An example is HLA-A11 allele which is frequent in East Asia where many circulating Epstein-Barr virus isolates are characterized by having an epitope presented by HLA-A11. It is important to note that in different organisms same antigens still can be presented, but the specific set of presented peptide fragments (of the same antigen) is determined by the specific haplotype in each individual. The collection of peptides associated with HLA is referred to as the human immunopeptidome (Murphy and Weaver, 2016; Specht et al., 2020).

A set of genes in the MHC I locus encodes nonclassical class I molecules which are expressed on specific cell types. For example HLA-G molecules are expressed on the fetal cells during pregnancy and are known to inhibit CD8 + T cells. Nonclassical MHC class II molecules include HLA-DM and HLA-DO molecules involved in antigen processing and presentation (Murphy and Weaver, 2016; Punt et al., 2018; Rich et al., 2018).

HLA inheritance is codominant (equal expression of haplotypes inherited from the mother and from the father) and follows Mendelian pattern in general (Fig. 3). That means that there is one-in-four chance of having the same paternal and maternal haplotypes for any two siblings, unless they are not identical twins. This makes them histocompatible with one another. However there is also chance of meiotic crossover responsible for about 1% probability of a new haplotype occurrence. Human haplotype initially was identified by mixing lymphocytes with different antisera, but each of serologically identified alleles can be typed by DNA-based methods (PCR or sequencing) which gives rise to a complicated nomenclature reflecting the diversity of HLA alleles in human population. A typical class I HLA haplotype designation thus can be exemplified as HLA-A*23:01:101:01:02N where numbers (which are unique for each haplotype) are used to specify allele group, specific HLA protein, synonymous nucleotide substitution within the coding region and non-coding region differences followed by a letter (in the example above, letter "N" which means "Null") denoting expression pattern. The number of HLA alleles is enormous, as stated above, but probably underestimated due to the low availability of genomic data from African, Indian and other regions (Murphy and Weaver, 2016; Punt et al., 2018; Rich et al., 2018).

Inbred mouse strains, in contrast to human population, are syngeneic and are homozygous at the MHC locus. For example, widely used C57BL/6 strain expresses H2^b haplotype which means that they always have the same set of K, A, E and D H2 alleles. If this strain is crossed with a CBA strain which haplotype is H2^k, the F1 generation will be designated as expresses H2^{b/k} (Murphy and Weaver, 2016).

Fig. 3 Inheritance of MHC (HLA) haplotypes. Maternal alleles are designated with letter 'm' and chromosome homolog number (1 or 2). Paternal alleles are designated with letter 'f' and chromosome homolog number. Note identical haplotypes in offsprings 3 and 5. A novel haplotype is recorded in child 6 as a consequence of meiotic recombination in father's chromosomes.

Fully heterozygous individual can express six unique MHC class I molecules on each cell. Remember that MHC class II molecules can form different α - β combinations and there are two DRB molecule types (DRB1 and one of extra DRB3 to DRB5 alleles encoded by DRB paralogue genes). However, Class II DRA allele is invariant and its structure is independent of maternal or paternal origin. Given all above, up to 12 unique class II molecules can be expressed on any single pAPC (Table 1) (Donaldson et al., 2015; Matern et al., 2020).

MHC functions

The diversity of antigens bound by T cell receptors somewhat reflects the diversity of peptides presented by MHC molecules. However, T cells provide recognition of antigen only in context of self MHC molecules. This phenomenon is explained by the term ‘MHC restriction’ which takes place during T cell development in the thymus. If MHC restriction did not exist, multiple ‘useless’ T cells would be differentiated. This T cells would have receptors able to recognize foreign MHC-peptide complexes which seems to be evolutionary impractical resource handling (energy and cell building materials). Despite the enormous diversity of T cell repertoire generated in thymocytes, only 1% survives after thymic selection and only T cells capable of interacting with self MHC are selected for further development. It is natural to conclude MHC restriction is a by-product of positive selection which primary function is to avoid supernumerary wandering lymphocytes generation. However, the inherent ability of T cells to recognize MHC molecules still allows the presence of some alloreactive T cells that recognize nonself MHC molecules as foreign and pose a problem in case of organ transplantation. Negative T cell selection process also makes sure that T cells are able to distinguish between self and non-self since thymocytes with excess affinity to self peptide-MHC complexes are discarded from entering the circulation (Murphy and Weaver, 2016; Punt et al., 2018; Rich et al., 2018).

Summarizing the above, presentation of foreign antigens to CD4+ or CD8+ T cells is a key function of MHC molecules that plays an indispensable role in fighting infection. However, MHC also maintains healthy functioning of an organism even in the absence of an infectious agent. Timing and location of MHC-TCR interactions thus plays crucial role for the consequences of such interaction. Constitutive expression of MHC class I displaying self peptide serves as a marker of healthy cell. It is also necessary to maintain tolerance to self proteins (Murphy and Weaver, 2016; Punt et al., 2018; Rich et al., 2018). It is no wonder then that some immunologists refer to MHC molecules as a “garbage bin” that allow T cells to develop in familiar conditions and to stay aware about the situation in the house.

Loss of MHC class I molecules is called ‘missing self’. Since NK cells have evolved inhibitory receptors activated upon MHC class I binding, the absence of MHC class I on nucleated cells signals that a cell should be destroyed by NK cells since some viruses interfere with MHC class I expression. At the same time, absence of MHC expression in red blood cells makes these cells a privileged site for such parasites as *Plasmodium*, *Babesia* and *Bartonella* (Murphy and Weaver, 2016; Punt et al., 2018; Rich et al., 2018).

It is clear now that different MHC alleles in humans are associated with a range of autoimmune and autoinflammatory diseases, e.g., rheumatoid arthritis, type 1 diabetes, systemic lupus erythematosus, ankylosing spondylitis, etc. However, the pathogenic mechanisms of these alleles are still unresolved. A number of hypotheses have been proposed to explain the contribution of MHC to the autoimmunity. Presentation of autoantigens or molecular mimicry of microorganisms and self antigens may play a role in some cases, while altered T cell repertoire during thymic selection may be another reason.

Table 1 Possible associations of human MHC genes.

MHC class	Origin of first chain	Origin of second chain	Number of possible molecules
Class I	Maternal HLA-A	N/A	3
	Maternal HLA-B		
	Maternal HLA-C		
	Paternal HLA-A	N/A	3

Endogenous antigen processing and presentation

Antigen presentation is required to initiate immunological responses mediated by antigen-specific T cells. Endogenous antigens, or antigens from intracellular locations are displayed on the surface of nucleated cells in complex with MHC class I molecules. MHC class I makes these otherwise internal antigens accessible for the CD8⁺ T cells. If these antigens recognized as foreign the cell becomes a target for the destruction.

Before antigen is displayed it should be processed. This event is coupled with MHC class I assembly and takes place in the cytosol and in the endoplasmic reticulum (ER). Self proteins are subject to constant turnover inside the cell and a large proportion of newly synthesized proteins are immediately degraded. This is particularly relevant to defective ribosomal products, or DRiPs, which originate from erroneous transcription, translation or protein folding and assembly. Some of the proteins are of viral origin if the cell becomes infected while some proteins recognized as foreign result from malignant cell transformation or aging. This immediate degradation of proteins is crucial for the rapid antiviral response and requires sufficient amount of readily available MHC class I molecules in the ER. Protein breakdown machinery that generates peptides suitable for MHC class I binding involves specific proteasome set: 26S proteasome, immunoproteasome or thymic proteasome depending on the cell type. A complex catalytic structure of proteasomes is represented by different subunits determining the type of the proteasome. Immunoproteasome is a specific type of proteasome which subunits are expressed in pAPCs or infected cells under the exposure to IFN- γ or TNF. The immunoproteasome is more efficient in production of peptides that bind MHC class I molecules since its enzymatic specificity differs from the 'ordinary' constitutive proteasome. Since excessive MHC class I presentation possibly can result in autoimmunity, the immunoproteasome is subject to a quick degradation itself (Specht et al., 2020).

Proteins are tagged for degradation by the ubiquitination process. In the context of cell life cycle, the MHC system can be viewed as an effective system of waste management (Nagy, 2008). In this system, peptides that are not fully degraded or reused and are not destroyed in the autophagy process are transported by MHC molecules out of the cell interior, at the same time providing signal to the T cells.

Peptides produced by proteasome usually occur through proteolytic reaction that requires ATP. However a fraction of the peptides released by proteasomes is formed through a transpeptidation reaction, thus adding a sizeable portion of spliced peptides to the ligand repertoire presented by MHC class I. A number of other modifications may occur, e.g., citrullination, phosphorylation, acetylation or deamidation contributing to neoepitope formation (Sun et al., 2014; Mei et al., 2020; Ostankovitch et al., 2009).

Some of the peptides processed by proteasomes are then picked up by ATP-dependent transporter associated with antigen processing (TAP). TAP is a heterodimer comprising TAP1 and TAP2 proteins. TAP1 and TAP 2 basically form channels across the ER membrane, through which peptides are ferried into the lumen. While TAP has the highest affinity for peptides composed of nine amino acids, it still can transport longer peptides into the lumen of the ER. Here, an additional trimming of the peptide may occur by ER-resident amino peptidases (ERAP1, or ERAAP), before a peptide is loaded onto the MHC. Peptides failing to associate with MHC may re-enter the cytosol by the ERAD (ER-associated protein degradation system) or Sec61 transport complex to undergo further modifications or degradation. ERAD system functions to clear misfolded MHC class I molecules out of the ER as well (Fig. 4) (Murphy and Weaver, 2016; Punt et al., 2018; Rich et al., 2018).

MHC class I molecules manufactured via ribosome synthesis are stabilized by chaperones—calnexin, calreticulin, endoplasmic reticulum p57 (ERp57), TAP-binding protein (also referred to as tapasin) and protein disulfide isomerase (PDI). Calnexin and ERp57 are required for the correct folding of the class I α chain. Upon β 2-microglobulin binding, calnexin dissociates to allow connection between ERp57- α chain complex and calreticulin, as well as tapasin to form the peptide loading complex (PLC). Tapasin is one protein that provides association of MHC class I with TAP transporter forming a bridge between these molecules. In a process referred to as peptide editing, PLC allows dynamic exchange of ER peptides inside the peptide-binding groove until a peptide with high affinity is selected. This affinity is partly determined by the presence of hydrophobic or basic residues at the carboxy terminus. Binding of a peptide to MHC class I molecules releases the chaperones allowing peptide-MHC complexes to leave the ER in a transporting vesicle for presentation at the cell surface. Since peptide still can suddenly dissociate from the MHC class I, this dissociation results in β 2-microglobulin release and MHC class I internalization. This internalization allows MHC class I molecules to enter the endosomal compartments where they can snatch away some peptides used in the MHC class II presentation pathway (Murphy and Weaver, 2016; Punt et al., 2018; Rich et al., 2018). This appears to be one of the mechanisms of cross-presentation described below.

Exogenous antigen processing and presentation

Exogenous antigens derive from outside the cell and thus should be internalized and digested before they are displayed on the cell surface. This processes are realized by APCs that can engulf foreign particles through phagocytosis or clathrin-dependent internalization. Professional APCs express a variety of accessory molecules (costimulatory receptors and cytokines) enabling them to arm T cells for the deployment of immune responses. Three types of pAPCs are known: dendritic cells, macrophages and B cells which differ in origin and manner of antigen handling. However, they all are similar in terms of MHC class II molecules expression, which are synthesized in the ER and pass on to Golgi complex and then to endosomes containing antigens.

Internalized peptides are subject to intracellular digestion by a set of cysteine proteases, or cathepsins, that constitutes peptide processing pathway for MHC class II binding. Processing is facilitated through disulfide bonds reforming by endosomal IFN- γ -induced lysosomal thiol reductase (GILT). Before fusion of MHC II-containing vesicles with an endosome, the newly synthesized

MHC class II molecules are protected from peptide binding by invariant chain (Ii) which forms a trimer stabilized by calnexin during assembly. Another molecule associated with MHC class II is HLA-DM coded in the MHC class II region. Fusion of an endosome and MHC class II-containing vesicle ultimately ends up in a late endosome formation where rapid pH decrease leads to the degradation of Ii-chain by proteases, leaving only a small CLIP fragment (class II-associated invariant chain peptide). CLIP remains bound to the peptide-binding groove, where HLA-DM supports its 'ajar' conformation. This allows CLIP release when a peptide with higher affinity for the peptide-binding groove approaches. Thus, HLA-DM serves to aid the exchange of CLIP with

antigenic peptides inside the groove and resembles peptide-editing role of PLC in MHC class I, ensuring tight binding of the peptide presented on the cell surface. Another nonclassical MHC molecule, HLA-DO, acts as a regulator of HLA-DM function and alters the repertoire of self-peptides presented by thymic epithelial cells (Fig. 5) (Murphy and Weaver, 2016; Punt et al., 2018; Rich et al., 2018).

Exogenous antigens can be found associated with MHC class I molecules, and vice versa, peptide fragments formed in cytosol can bind to MHC class II molecules suggesting that processing pathways are not limited by above described pathway. Notably, cytosolic peptides, including self peptides can be loaded onto MHC class II complex as a result of autophagy. Moreover, successful antiviral response does not solely depend on the MHC class II presentation to engage helper T cells that provide more powerful antiviral response but requires arming of CD8+ T cells via class I molecules. This phenomenon is termed as cross-presentation which is carried out by a subset of CD8 α -expressing dendritic cells or macrophages (Muntjewerff et al., 2020). However, cross-presentation not only used in naïve CD8+ T cell activation (i.e. cross-priming) but is also indispensable to support proper dendritic cell functioning. This is explained as a dendritic cell licensing model where dendritic cell, to be fully activated, requires corresponding signaling from the T helper cell. Taking into account that autoreactive T helper cells are discarded in thymus or become inactive due to the peripheral tolerance mechanisms, dendritic cells licensing provides a mechanism to avoid tolerance breakdown in case

Fig. 5 Exogenous antigen processing and presentation. British Society of Immunology, 2013 (<https://www.immunology.org/public-information/bitesized-immunology/systems-and-processes/antigen-processing-and-presentation>).

self antigen is presented to CD8+ T cell. Once a dendritic cell acquires a stimulatory signal from T helper cell (via cytokine milieu or costimulatory molecules), it becomes capable to activate naïve CD8+ T cells. Otherwise, dendritic cell may provide inhibitory signal to CD8+ T cell to maintain tolerance to self antigens. This is crucial given the fact that dendritic cells constantly present self-peptides originating from dying cells and other sources. Another mechanism proposed to explain self tolerance in case autoantigens are presented is that accidental priming, or activation of CD8+ autoreactive T cell by a dendritic cell will result in a rapid cytotoxic lysis of the dendritic cell, preventing it from further contact with CD8+ T cells (Abbas et al., 2019; Male et al., 2020).

MHC class II molecules can be internalized from the cell surface in case they lose antigen or due to the ordinary recycling process. However, the MHC class II recycling halts in mature dendritic cells upon pathogen encounter. This is mediated by inhibiting the membrane associated ring finger (C₃HC₄)₁ (MARCH-1) protein. MARCH-1 protein is a ligase that targets cytoplasmic tails of MHC II class providing their recycling. Thus, MARCH-1 inhibition ensures lock-on of MHC class II recycling to keep peptide-MHC II complexes on the cell surface upon infection, which is necessary for T cell activation (Abbas et al., 2019; Male et al., 2020).

Nonclassical MHC molecules and presentation of nonpeptide antigens

A scavenger theory of MHC molecules would suggest that a set of molecules discarded from cell should not be limited by peptide molecules. Indeed, there is a class of molecules structurally similar to classical MHC class I molecules capable to display lipid or lipid-linked molecules. These protein families are designated as CD1 and MR1 (MHC class I-related protein) which are expressed by a variety of cells, including APCs and non-immune cells. In contrast to MHC class I, these molecules are coded outside of MHC locus and are not characterized by pronounced polymorphism. A set of CD1-restricted cells is known to recognize the lipid antigens bound to these nonclassical MHC molecules. Among antigens presented via these pathway is mycolic acid from *Mycobacterium tuberculosis* and other Mycobacteriaceae. A fact that a very conserved subtype of T cells which is abundant in skin and mucosa is required to recognize a specific molecule reflects a long history of co-evolution of human immune system and mycobacteria. MR1 displays metabolites of folic acid that are recognized by mucosal associated invariant T cells (MAIT cells) bearing homodimeric CD8 $\alpha\alpha$ co-receptor (Abbas et al., 2019; Male et al., 2020).

Another nonclassical MHC molecule is Qa-1 in mice and its functional homolog in humans, HLA-E. It presents peptides when the function of ERAP1 is inhibited, which can be a consequence of viral infection or tumor transformation. Peptides presented by Qa-1 are conserved and provide signal for CD8+ T cells, preventing pathogens or tumor cells from immunosurveillance evasion (Nagarajan et al., 2012).

TCR-MHC interactions during presentation

Recognition of peptide-MHC complex by the T cell receptor (TCR) provides essential first signal for the T cell activation and the development of immune response. Conventional $\alpha\beta$ TCRs are antigen-recognition molecules that are highly variable and somewhat resemble the structure of an immunoglobulin Fab fragment. Each T cell expresses about 30,000 identical TCRs on the cell surface. TCRs bind short peptide sequences that are usually inaccessible in the native protein structure. Thus, antigen processing and presentation makes these sequences available for TCR recognition. However, TCR reacting with its ligand is also making contacts with the MHC molecule α domains. TCR α chain contacts with $\alpha 2$ domain of class I molecules while TCR β chain contacts with $\alpha 1$ domain. TCR orientation along MHC molecules allows binding of CDR1–CDR3 loops to come in close contact with the presented peptide via slight conformational changes within the CDR loops. While initial stages of the contact are determined by TCR-MHC molecules, subsequent peptide recognition depends on adoptive conformational changes that will affect T cell response. Depending on the type of cells, CD4 or CD8 molecules become associated with TCR when the process of antigen-recognition initiates. CD8 binds to the invariant fragment of MHC class I $\alpha 3$ chain while CD4 binds to such fragment of MHC class II located between $\alpha 2$ and $\beta 2$ domains. Acting as co-receptors, CD4 and CD8 profoundly increase T cell sensitivity to antigen. Once antigen is recognized, other co-stimulatory molecules and cytokines are expressed for the full activation of the T cell (Abbas et al., 2019; Male et al., 2020).

Antigen presentation in thymus

Generation of T cell repertoire requires thymic development where the processes of positive and negative selection ensure self MHC restriction and rejection of autoreactive cells. Starting at the stage of double-positive thymocytes, T cell development substantially depends on TCR-MHC interactions. Double-positive (CD8+/CD4+) thymocytes rely on recognition and binding of self-peptide MHC in order to survive; a process referred to as positive selection. Timing of this interactions coincides with gradual migration of thymocytes from thymic cortex to cortico-medullar region. Here cortical epithelial cells expressing MHC class I and class II reside. Cortical epithelial cells express a set of cathepsins and thymic proteasome distinguishing them from other antigen-presenting cells. Also, they express a significant number of MHC class II that keep binding CLIP. Hence, successful binding to MHC class I or class II is determined by inherent specificity of TCR to MHC molecules rather than their peptide specificity. In contrast, negative selection is provided by screening T cells that bind self antigens with high affinity; these T cells die by apoptosis. Processing of tissue-specific peptide that are expressed in the thymus is driven by autoimmune regulator (*AIRE*) gene which allows expression and presentation of peptides otherwise expressed only outside of the thymus. Cells responsible for negative selection are the thymic epithelial cells, bone marrow-derived dendritic cells and macrophages (Abbas et al., 2019; Male et al., 2020).

Successful positive and negative selection leads to cessation of CD4 or CD8 expression and shutting off TCR α -chain rearrangement. However, the 'second' TCR with a productively rearranged α -chain still can be expressed due to the absence of allelic exclusion in genome during TCR α -chain rearrangement. In mature T cells this TCR is mostly internalized due to the weak or excessively strong peptide-MHC binding, thus maintaining so-called phenotypic allelic exclusion and providing functional monospecificity (Schuldt and Binstadt, 2019). Thymocytes that survive positive and negative selection in the cortex relocate to the medulla as single positive thymocytes where they encounter a new assemblage of self-peptide-MHC. High-affinity interactions here lead to clonal deletion. However, a number of T cells with high affinity to self peptide-MHC survive through the process called agonist selection and give rise to Treg cells (Stritesky et al., 2012).

The role of MHC-mediated T cell selection and tolerance is not limited within the thymus. At the periphery, self peptide-MHC complexes provide tolerogenic signals to eliminate or inactivate autoreactive mature naïve T cells.

MHC-associated immunodeficiencies

Autoimmune diseases comprise only a part of diseases associated with improper MHC functioning. Another large pool of diseases is immunodeficiencies which originate from absence or improper function of certain components involved in antigen processing and/or presentation. Immunodeficiencies manifest as different infections depending on the affected genes. These diseases are classified into different types, e.g., MHC class I deficiency and MHC class II deficiency group A, B, C, D belong to a group of 'Immunodeficiencies affecting cellular and humoral immunity'. They are characterized by genetic defects in *TAP1*, *TAP2*, *B2M*, *CIITA* or other genes directly involved in MHC synthesis and assembly. APECED (APS-1), autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy is a consequence of AIRE defect and is classified into 'Diseases of immune dysregulation' (Tangye et al., 2020). Many immune defects, e.g., ubiquitin system mutations, are not included into the immunodeficiency classification, however they still manifest by impaired immune responses (Etzioni et al., 2017).

Glossary

Antibody An antibody is a protein that binds specifically to a particular substance, termed antigen. All antibodies have the same overall structure and are known collectively as immunoglobulins or Igs. They belong to the immunoglobulin superfamily. Antibodies are produced by plasma cells in response to infection or immunization. Antibodies bind to pathogens and prepare them for ingestion and destruction by phagocytes.

Antigen An antigen is any molecule that can bind specifically to an antibody. The term antigen arises from the ability these substances have to generate antibodies. However, some antigens do not, by themselves, evoke antibody production and they are called haptens. Antigens that can induce antibody production by themselves are called immunogens.

Apoptosis Apoptosis is a form of cell death, also known as programmed cell death. It is a 'suicide' program that activates within the cell. This program starts with DNA fragmentation, followed by shrinkage of the cytoplasm, membrane modifications, and finally, cell death without lysis or harm to neighboring cells. It is a normal phenomenon, frequently occurring in a multicellular organism. Proliferating cells usually undergo apoptosis, as part of the natural development process. Also, dividing lymphocytes undergo apoptosis at high rates during development, and during immune responses. Apoptosis contrasts with necrosis cell death, which occurs in circumstances such as anoxia or poisoning. Phagocytes remove apoptotic cells by phagocytosis.

Chemotaxis Process by which phagocytes migrate towards places of infection.

Complement A complement system is a group of plasma proteins that together attack extracellular forms of pathogens. Complement activation can occur spontaneously on some pathogens or by antibody binding to the pathogen. Complement components are deposited on the membrane of the pathogen forming a molecular complex (the membrane attack complex) that forms pores on the membrane. With this, the cell is destroyed by osmotic shock. Complement proteins deposited on pathogens are recognized by phagocytes to remove pathogens via phagocytosis.

Dendritic cells Dendritic cells are bone marrow-derived cells with branched or dendritic morphology, located in lymphoid tissues. They are antigen-presenting cells and the most potent stimulators of T-cell responses.

Fc receptors Fc receptors are receptors for the Fc portion of antibodies. They are named according to the class of antibody they recognize. So Fc γ receptors bind IgG, Fc α receptors bind IgA, and Fc ϵ receptors bind IgE.

Immunoglobulin All antibody molecules belong to a family of plasma proteins called immunoglobulins (Ig). Membrane-bound immunoglobulin serves as the specific antigen receptor on B lymphocytes.

Integrins Integrins are heterodimeric cell-surface proteins involved in cell–cell and cell–matrix interactions. They are essential in adhesive interactions between lymphocytes and antigen-presenting cells and in lymphocyte and leukocyte migration into tissues.

Macrophages Macrophages are large mononuclear phagocytic white blood cells. They are migratory cells deriving from bone marrow precursors found in most tissues of the body. They have a crucial role in host defense.

Monocytes Monocytes are white blood cells with a bean-shaped nucleus. They are macrophages precursors.

Neutrophils Neutrophils are the most abundant type of white blood cell in circulation. They have a multilobed nucleus and multiple granules. They are also known as neutrophilic polymorphonuclear leukocytes. Neutrophils are phagocytes that ingest and kill extracellular pathogens.

Opsonization Process where some plasma components, such as antibodies or complement proteins, cover a pathogen. In doing so, they intensify the process of phagocytosis by neutrophils and macrophages.

Phagocyte A phagocyte is a cell that performs phagocytosis. There are two types of phagocytes: professional and nonprofessional. Professional phagocytes include dendritic cells, eosinophils, macrophages, monocytes, neutrophils, and osteoclasts. Nonprofessional phagocytes include endothelial cells, epithelial cells, and fibroblasts.

Phagocytosis Phagocytosis is a cellular process for ingesting and eliminating particles larger than 0.5 μm in diameter, including microorganisms, foreign substances, and apoptotic cells.

Phagolysosome Phagolysosome is a large vacuole formed from the fusion of the phagosome with one or more lysosomes. The lysosome contains lytic enzymes that are essential in pathogen destruction and degradation to small molecules.

Phagosome The phagosome is a vacuole that forms when extensions of the cell membrane cover and external particle and ingest it into the cell.

Phagocytosis history

Science is supported on fundamental discoveries. One of the main problems to solve during the nineteenth century was, how do we fight infections? There was a major controversy about how the body fights infections. Some people believed it was the humoral immunity (i.e., antibodies) the answer to fight pathogens. Other thought that it was the cellular immunity (i.e., white blood cells) the way to eliminate pathogens. Paul Ehrlich (1854–1915) was the humoral immunity theory leader, and Elie Metchnikoff (Ilya Ilyich Metchnikov; 1845–1916) was the cellular immunity leader. Metchnikov was a Russian pathologist that defined phagocytosis as a defense mechanism (Cavaillon and Legout, 2016). As it turns out both researchers were right. We now know that both arms, the cellular and humoral responses cooperate to fight infections. Elie Metchnikoff shared the Nobel prize in Physiology or Medicine in 1908 with Paul Ehrlich, recognizing this way that together they provided the bases for modern immunology.

First observations for phagocytosis

Elie Metchnikoff was not the first person to observe and report the process of phagocytosis (Table 1), but his deep understanding of the phenomenon let him to outstanding contributions in the field (Cavaillon and Legout, 2016; Rosales, 2018). In the nineteenth century Alexander Ecker, Nathanael Lieberkühn, Giulio Bizzozero saw erythrocytes inside cells (Table 1). Sir William Osler saw carbon particles inside cells while Robert Koch, Paul Albert Grawitz and Alexander Ogston saw bacteria and fungi inside cells (Table 1) (Cavaillon and Legout, 2016; Rosales, 2018).

Phagocytosis theory

During a vacation with his family, Metchnikoff made his original observations in the 1880s while studying marine invertebrate organisms. He stuck rose thorns into starfish larvae and was astonished to see that many special cells were attacking the small thorns (Metchnikoff, 2015; Vikhanski, 2016). Based on his observations, he started realizing that phagocytosis was a defense mechanism. In 1883, he published a paper describing the phagocytosis process (Tauber, 2003). In this publication, he used the word phagocyte, from “phago” (eating) and “cyte” (cell). This term was suggested to Metchnikoff by his friend Carl Friedrich Wilhelm Claus (Cavaillon and Legout, 2016) (Table 2). Succeeding, he moved into immunology and championed the concept of cellular immunity (Metchnikoff, 1890; Cavaillon, 2011). The dispute about humoral and cellular immunity was challenging. There were

Table 1 Initial observations of phagocytosis (Cavaillon and Legout, 2016; Rosales, 2018).

Year	Scientist	Observations
1847	Alexander Ecker	Identified red blood cells (erythrocytes) inside rabbit spleen cells.
1870	Nathanael Lieberkühn	Stated that white blood cells (leukocytes) could ingest red blood cells (erythrocytes).
1871	Giulio Bizzozero	Presented the first pictures of macrophages that had ingested erythrocytes.
1874	Peter Ludwig Panum	Proposed that cell ingestion might represent a method of defense.
1875	Sir William Osler	Reported the intake of carbon particles within alveolar macrophages of miners.
1876	Robert Koch	Identified anthrax bacilli in leukocytes. He believed that the bacteria had invaded the host cells and not that the cells had ingested the bacteria.
1877	Paul Albert Grawitz	Observed that leukocytes ingest fungi.
1881	Alexander Ogston	Described that groups of cocci were inside cells. Introduced the word “ <i>Staphylococcus</i> ” (from the Greek word staphyle) to describe these bacteria resembling a bunch of grapes.

Table 2 Metchnikoff contributions to phagocytosis (Cavaillon and Legout, 2016; Rosales, 2018).

Year	Observations
1882	"If a delicate glass tube, a rose thorn, or a spine of a sea urchin be introduced into one of these larvae, the amoeboid cells of the mesoderm collect around the foreign body in large masses easily visible with the naked eye".
1883	Introduced the term phagocyte in his publication. Described the role of phagocytes during the metamorphosis of tadpole to frog and the disappearance of the tail. Described the process of phagocytosis against foreign microorganisms.
1884	Described the role of phagocytes in daphnia fighting fungal pathogens and in frogs exposed to anthrax bacilli.
1890	Demonstrated that phagocytosis was mainly a function of the microphages (neutrophils).

Table 3 Other observations that supported the phagocytic theory (Bordet, 1886; Gabritschevsky, 1894; Mesnil, 1896; Tchistovitch and Yourevitch, 1908; Tauber and Chernyak, 1989; Cavaillon and Legout, 2016; Rosales, 2018).

Year	Scientist	Observations
1894	George Gabritschevsky	Demonstrated that in rabbits immunized with diphtheria bacilli were within phagocytes 8 h after inoculation of the bacilli. In contrast, in non-immunized rabbits there were still free bacteria. Introduced the word pinocytosis to describe the engulfment of soluble substances.
1896	Félix Mesnil	Demonstrated that in guinea pigs injected subcutaneously with <i>Vibrio cholera</i> the contribution of phagocytosis was much larger than any effect due to humors.
1886	Jules Bordet	Established that phagocytosis was easily observable <i>in vitro</i> .
1901	Ivan Himmel	Reported that by 24 h after injection of <i>Haemophilus ducreyi</i> into guinea pigs, most bacilli had been phagocytized. Intraperitoneal injection of pus from patients infected with <i>Neisseria gonorrhea</i> , guinea pig leukocytes could absorb both free gonococci in pus, and also human leukocytes packed with gonococci. Confirmed that phagocytes could ingest not only microorganisms but also complete cells.
1908	Nicolai Tchistovitch	Demonstrated that the cells responsible for trapping via phagocytosis dust particles in the lung alveoli were alveolar macrophages and not epithelial cells. Found that rabbit alveolar macrophages could phagocytize <i>Erysipelothrix rhusiopathiae</i> and <i>Bacillus anthracis</i> , but not <i>Pasteurella multocida</i> . Coined the word "antiphagin", and showed that pneumococci display a similar capacity to resist phagocytosis.

many opponents to the phagocytic theory, but followers of this theory showed more evidence that supported it (Table 3). Immunization experiments performed by George Gabritschevsky in rabbits; Félix Mesnil and Ivan Himmel in guinea pigs showed that microorganisms were phagocytized by white blood cells (Gabritschevsky, 1894; Mesnil, 1896). Jules Bordet showed *in vitro* phagocytosis (Bordet, 1886) and Nicolai Tchistovitch explore phagocytosis in the respiratory system, showing that macrophages were capable of ingesting dust particles (Tchistovitch and Yourevitch, 1908; Tauber and Chernyak, 1989; Cavaillon and Legout, 2016; Rosales, 2018). However, even though phagocytosis was widely accepted after Metchnikoff won the Nobel prize, its importance was not appreciated until the 20th century.

Phagocytes

There are two types of phagocytes, professional and nonprofessional. Some phagocytes perform phagocytosis very efficiently and were therefore named professional phagocytes by Rabinovitch. These phagocytes include dendritic cells, eosinophils, macrophages, monocytes, neutrophils, and osteoclasts (Rabinovitch, 1995). Professional phagocytes are in charge of eliminating microorganisms and presenting them to cells of the adaptive immune system. Nonprofessional phagocytes include endothelial cells, epithelial cells, and fibroblasts. These cells cannot ingest microorganisms but are essential in eliminating apoptotic cells (Flannagan et al., 2012; Gordon, 2016).

The process of phagocytosis

Phagocytosis is an essential process for nutrition in unicellular organisms. In contrast, in multicellular organisms, just some cell types phagocyte. These cells are called phagocytes. Phagocytes can ingest microbial pathogens, but notably also apoptotic cells. In this way, they contribute to tissue homeostasis by eliminating billions of cells that die every day. Cells use phagocytosis to capture, ingest and destroy all particles larger than 0.5 μm , including cellular fragments and microorganisms.

To understand phagocytosis, we will divide it into steps.

Step 1. Particle recognition: Phagocytes have to recognize the particle to be ingested by using specific receptors (Freeman and Grinstein, 2014). These receptors cooperate for an efficient recognition of the target particle. First, receptors must engage multiple

ligands on the target particle and for achieving this, the receptors must be capable of moving fast in the membrane so that they can aggregate around the target (Rosales and Uribe-Querol, 2017).

Step 2. Particle ingestion: Phagocytic receptors initiate a cascade of signals, change lipids in the cell membrane, and organize the actin cytoskeleton to grow the cell membrane around the particle to be ingested (Freeman and Grinstein, 2014).

Step 3. Early phagosome formation: A phagosome is the vacuole formed to bring the particle inside the cell. Receptors work together in sequential order and cooperate to form the phagosome (Ostrowski et al., 2016). The phagosome rapidly fuses with early endosomes to change its membrane composition.

Step 4. Late phagosome formation: This process happens when the early phagosome fuses with vesicles coming from the endoplasmic reticulum, and the Golgi complex (Wähe et al., 2010; Campbell-Valois et al., 2012; Nunes et al., 2012; Guido et al., 2015).

Step 5. Phagolysosome formation: This process is the fusion of an intermediary phagosome with lysosomes and changing the membrane and interior components. The phagosome turns into a microbicidal vacuole, the phagolysosome (Fairn and Grinstein, 2012; Niedergang and Grinstein, 2018).

Step 1. Particle recognition: Phagocytosis receptors

Phagocytes must recognize many different particles that could potentially be ingested, including all classes of pathogens and dying cells. Phagocytes investigate their surroundings for phagocytic particle targets by extending finger-like membrane projections called filopodia. Various receptors on the plasma membrane of phagocytic cells recognize these particles and then initiate the process of phagocytosis. A single phagocyte can express several receptor types, and they cooperate for the recognition and ingestion of the particle. Phagocytic receptors are classified as non-opsonic receptors or as opsonic receptors. Non-opsonic receptors can directly recognize pathogen associated molecular patterns (PAMPs) and also activate the phagocytosis process (Table 4) (Uribe-Querol and Rosales, 2020). These receptors include C-type lectins, such as Dectin-1 (Dambuza and Brown, 2015), Dectin-2, DC-SIGN and Mincle; and also scavenger receptors (Canton et al., 2013). Toll-like receptors (TLRs) can also detect molecular patterns on pathogens, but they are not phagocytic receptors (Kawai and Akira, 2011). However, TLRs can cooperate with phagocytic receptors to make the phagocytic process more effective (Iwasaki and Medzhitov, 2015).

Opsonic receptors recognize host-derived soluble molecules that bind to foreign particles and target them for ingestion (Table 5). These soluble molecules are called opsonins and include antibodies, complement, fibronectin, mannose-binding lectin, and milk fat globulin (lactadherin) (Flannagan et al., 2012) (Table 5; Fig. 1A and B).

Fig. 1 Particle recognition and cooperation among phagocytic receptors. (A) Opsonization process with antibodies. (B) Opsonization process with complement molecules. (C) Phagocytic receptors, like opsonic receptors for antibody (Fc γ RIIA) and for complement (Integrin CR3) are tiny molecules of only few nanometers. In contrast, transmembrane glycoproteins, such as phosphatases CD45RO and CD45RA, are much longer molecules, of about 40–90 nm, and are usually rigid molecules. (D) At resting state, receptors cannot diffuse freely throughout the membrane. Their movement is restricted by fences of transmembrane glycoprotein attached to an actin mesh. (E) Cooperation among phagocytic receptors. Most phagocytic receptors, such as Fc γ RIIA and receptors for complement (Integrin CR3) cooperate to bind the particle to be ingested. Fc γ R aggregation triggers an inside-out signal that activates integrins (dashed arrow).

By a process of opsonization, antibodies or complement proteins, cover a pathogen and can be recognized by specific receptor on phagocytes (Fig. 1A and B). Antibody receptors and complement receptors (CR) are some of the most studied phagocytic receptors. Antibody receptors are also called Fc receptors (FcR) and are a family of proteins expressed on white blood cell (leukocytes) membranes (Rosales, 2007). FcR bind the Fc portion of antibodies and can induce phagocytosis and other cellular responses (Nimmerjahn and Ravetch, 2011; Rosales and Uribe-Querol, 2013a, b, 2017). Complement receptors recognize the complement components, such as iC3b, deposited on phagocytic targets surfaces (van Lookeren Campagne et al., 2007). There are three types of complement receptors: (1) The immunoglobulin Ig-superfamily member CR1g (Helmy et al., 2006). (2) The short consensus repeat (SCR) modules that code for CR1 and CR2 (Tohyama and Yamamura, 2006; Rosales, 2007). And (3) the $\beta 2$ integrin family members CR3 and CR4 (Tohyama and Yamamura, 2006; Rosales, 2007) (Table 5).

Many cells from our body start a cell dead program called apoptosis. Cells enter apoptosis when they are faulty or when they are no longer needed for a certain function. Apoptosis is a way to get rid of defective cells, but the dead cells must be eliminated in order to maintain homeostasis. Phagocytes are also responsible for removing apoptotic cells. Apoptotic cells release molecules (ATP, lysophosphatidylcholine, and sphingosine 1-phosphate) that function as attractants (chemoattractant) for phagocytes. Apoptotic cells also start expressing molecules on their membrane surface, such as phosphatidylserine and oxidized lipids, that are not normally on the external part of the membrane. These molecules function as an “eat me” signal for phagocytes. There are specific receptors that recognize apoptotic cells such as TIM and stabilin-2 (Table 4) (Rosales and Uribe-Querol, 2017; Uribe-Querol and Rosales, 2020).

Step 2. Particle ingestion: Intracellular activation and actin cytoskeleton

Phagocytes investigate their surroundings for particles to ingest by extending filopodia. These membrane projections covered with receptors contain principally linear actin. When a particle interacts with phagocyte receptors, a signaling cascade inside the cell is triggered to activate particle ingestion. Phagocytic receptors aggregate and cooperate for an efficient recognition of the target particle. The cooperation depends on receptors binding affinity and their relative mobility within the membrane (Patel and Harrison, 2008; Flannagan et al., 2010). Most phagocytic receptors, like receptors for complement (Integrin CR3) and receptors for antibody (Fc γ RIIA), are small molecules that lengthen only a few nanometers from the plasma membrane (Fig. 1C). Glycoproteins like CD45 are much longer and stiff molecules (Fig. 1C). In the resting state, phagocytic receptors cannot diffuse freely throughout the membrane (Fig. 1D). Glycoproteins are attached to an actin mesh that restricts receptor movement (Fig. 1D). Receptors also cooperate to ingest particles. Fc γ R aggregation triggers an inside-out signal that activates integrins (Fig. 1E). Thus, particle recognition by receptor binding and activation are very active processes.

After phagocyte receptors bind to the target, their activation leads to changes in the membrane and the actin polymerization (Fig. 2). At the contact point, the membrane curves and forms a structure called the phagocytic cup. As more phagocytic receptors get engaged around the particle, the cell extends pseudopodia with branched actin fibers around the particle. Next, within a few minutes, the membrane surrounds the particle, leaving a new phagosome formation (Fig. 2).

Actin remodeling is crucial in particle ingestion. The steps of actin remodeling during phagocytosis are as follows. After a target particle is detected, the membrane-associated actin needs to be depolymerized (Fig. 2A). Then, nucleation and actin filament polymerization take place in order to extend pseudopodia around the particle. The Arp2/3 protein complex mediates actin nucleation and actin polymerization (Prehoda et al., 2000) (Fig. 2B). Finally, actin depolymerizes from the phagocytic cup base and polymerizes at the pseudopodia distal end (Fig. 2C). At this distal point is where the membrane will close forming the new phagosome (Fig. 2D), which will detach from the plasma membrane (Fig. 2E) (García-García and Rosales, 2002; Rosales, 2007; Rosales and Uribe-Querol, 2017). After phagosome detachment, the plasma membrane returns to its initial state (Fig. 2F).

Soon after phagosome formation, the process of phagosome maturation starts. This process comprises the events for a phagosome to become a phagolysosome. The process involves successive fusion and fission interactions between the new phagosome and other vesicles called endosomes and lysosomes. At the end of the process, the phagolysosome is a vesicle capable of destroying the particle ingested. It contains a very acidic and degradative contents (Fig. 3) (Fairm and Grinstein, 2012; Canton, 2014).

Step 3. Early phagosome formation

Early Phagosome. The new phagosome quickly gets the characteristics of early endosomes. It fuses with sorting and recycling endosomes (Levin et al., 2016). Membrane fusion between the phagosome and endosomes requires Rab5 (Fig. 3B). This protein is a membrane small GTPase. With the fusion, the interior of the early phagosome becomes a little acidic (pH 6.1–6.5). Nevertheless, this it is not very harmful to microbial pathogens inside the phagosome. The transition from an early to a late phagosome requires Rab5. EEA1 is another protein of the early phagosome that recruits proteins like Rab7 (Christoforidis et al., 1999). Even though many early endosomes fuse to the new phagosome, its size does not change. The size is maintained due to retrieving recycling vesicles to endosomes and to the trans-Golgi network (Fig. 3). The phagosome interior becomes more acidic as a result of the gradual accumulation of active V-ATPase proteins on its membrane. The V-ATPase is an enzyme that moves protons (H⁺) into the interior of the phagosome, using ATP from the cytoplasm as an energy source (Marshansky and Futai, 2008) (Fig. 3). As the phagosome matures, Rab5 is lost, and Rab7 appears on the membrane (Vieira et al., 2003). Rab7 is also a small membrane GTPase. Membrane fusion between the phagosome and endosomes requires Rab7 (Fig. 3C).

Fig. 2 Particle ingestion. (A) FcγRIIA target particle recognition and the actin cytoskeleton is disrupted at the site where the phagocytic cup starts to develop. (B) The cell extends pseudopodia, which contain new branched actin fibers. (C) Pseudopodia grows and forms the phagocytic cup. (D) The membrane surrounds the particle and fuses at the distal end. (E) New phagosome detach from the plasma membrane. (F) At the last step, depolymerization of actin filaments from the base of the nascent phagosome may facilitate curving of the membrane around the particle and provide room for fusion of internal vesicles, a source of endomembranes.

Step 4. Late phagosome formation

Early to late phagosome formation requires Rab5, but this molecule is lost from the membrane at the late stage (Kitano et al., 2008; Gutierrez, 2013). Instead, Rab7 accumulates and becomes a marker for the late phagosome stage formation. Rab7 recruits new proteins like Rab-interacting lysosomal protein (RILP) (Fig. 3B and C). RILP mediates the fusion between the late phagosomes and lysosomes (Jordens et al., 2001; Harrison et al., 2003). Also, the late phagosome recruits more V-ATPase. The increasing number of this ATPase contributes to a more acidic (pH 5.5–6.0) interior of this later stage of phagosome maturation (Kinchen and Ravichandran, 2008) (Fig. 3). Finally, the late phagosome also recruits lysosomal-associated membrane proteins (LAMPs) and luminal proteases (cathepsins and hydrolases) (Fig. 3C) (Fairn and Grinstein, 2012; Canton, 2014).

Step 5. Phagolysosome formation

The phagolysosome formation in the last stage in the maturation process. This step involves the fusion of late phagosomes with lysosomes. The phagolysosome is the final microbicidal organelle (Levin et al., 2016). It possesses various complicated mechanisms

Fig. 3 Phagolysosome maturation. After particle ingestion (A), the new phagosome gets transformed into a phagolysosome by sequential interactions with endosomes and lysosomes. Phagolysosome maturation can be described in three stages: early phagosome (B), late phagosome (C), and phagolysosome (D). In this maturation process, membrane changes to include molecules that control membrane fusion, such as the GTPases Rab5 and Rab7. During maturation stages, these vesicles become more acidic by the action of a proton-pumping V-ATPase. Also different degradative enzymes, such as cathepsins, proteases, lysozymes, and lipases are in charge of degrading microbes. *EEA1*, early endosome antigen 1; *LAMP*, lysosomal-associated membrane protein; *RILP*, Rab-interacting lysosomal protein; *NADPH*, nicotinamide adenine dinucleotide phosphate oxidase.

directed to eliminate and degrade microorganisms. V-ATPase molecules on its membrane continues to accumulate, so the phagolysosome interior is highly acidic (pH as low as 4.5) as more protons (H⁺) are translocated into the lumen of the phagosome (Marshansky and Futai, 2008). The acidic content of the phagosome creates an adverse environment for most microorganisms. The low pH obstructs the normal metabolism of several bacteria and fungi and prevents the use of many essential microbial nutrients (Jabado et al., 2000). Phagolysosome also contains many hydrolytic enzymes. Some of these enzymes are various cathepsins, proteases, lysozymes, and lipases (Kinchen and Ravichandran, 2008). Other recruited molecules at this point are scavenger proteins (Fig. 3). Scavenger proteins can kill bacteria because they sequester important nutrients for the bacteria. For example, the scavenger protein lactoferrin traps the iron required by some bacteria to live (Masson et al., 1969) (Fig. 4). The phagolysosome also produces

Fig. 4 Inside a phagolysosome. Very low pH is detected inside phagolysosomes. The low pH depends on the V-ATPase, that translocates protons (H⁺) into the lumen of the phagosome. Reactive oxygen and nitrogen species are produced. The NADPH oxidase is an enzymatic complex that produces superoxide (O²⁻). H₂O₂ can react with O₂ to generate other radicals, such as hydroxyl radicals (OH[•]). Myeloperoxidase (MPO) can transform H₂O₂ into HOCl. Also, nitric oxide radicals (NO[•]) are produced by the activation of the nitric oxide synthase 2 (iNOS). NO[•] reacts with O²⁻ and forms ONOO⁻. Lactoferrin captures Fe²⁺ that is essential for bacterial growth. Proteases and lysozyme degrades cell wall peptidoglycan of the bacteria. Red arrows are harmful molecules for the bacteria. Black arrows are chemical reactions or proton movements.

reactive oxygen species (ROS) and reactive nitrogen species. It recruits NADPH oxidase (Panday et al., 2015), a protein complex that produces superoxide ($O_2^{\cdot-}$) (Babior, 2004). Superoxide can dismutate to hydrogen peroxide (H_2O_2). In turn, H_2O_2 can react with $O_2^{\cdot-}$ to generate other radicals, such as hydroxyl radicals ($OH^{\cdot}$) and singlet oxygen (Winterbourn, 1995; Minakami and Sumimoto, 2006). The myeloperoxidase enzyme combines H_2O_2 with Cl^- ions into hypochlorous acid (HOCl) (Nauseef, 2014) (Fig. 4). The various forms of ROS can damage DNA, proteins and lipids of microorganisms (Lam et al., 2010). Also, peroxynitrite ($ONOO^-$) an extremely reactive specie, is formed by combining $O_2^{\cdot-}$ with nitric oxide radicals ($NO^{\cdot}$). Nitric oxide radicals are produced by the nitric oxide synthase 2 (Bogdan et al., 2000). This enzyme converts arginine and oxygen into citrulline and $NO^{\cdot}$ (Fig. 4). $NO^{\cdot}$ is produced on the cytoplasmic side of phagosomes, but it can diffuse across membranes and accumulate inside the phagosome (Webb et al., 2001). As mentioned earlier, once inside the phagosome, $NO^{\cdot}$ can react with $O_2^{\cdot-}$ to generate the highly toxic peroxynitrite ($ONOO^-$) that can alter proteins and DNA of ingested microorganisms (Richardson et al., 2009, 2011). Also, $NO^{\cdot}$ can directly impair bacterial enzymes and affect microbial growth (Grosser et al., 2016).

Conclusion

Phagocytosis is a complex and elegant process performed by specific cells called professional phagocytes. These cells include monocytes, macrophages, neutrophils, dendritic cells, osteoclasts, and eosinophils.

Phagocytosis is crucial for pathogen elimination, dying cell elimination, tissue homeostasis, and control of essential inflammation aspects.

We have presented the main steps of phagocytosis to provide a global picture of the whole process. There are still many questions unanswered about the details of how the final phagolysosome completes its killing functions.

Introduction

A concept of dendritic cells (DCs) as a distinct subpopulation of phagocytes was introduced by Ralph Steinman in his seminal work (Steinman, 1991), however many tissue-specific DCs have been discovered decades before. DCs are a class of antigen presenting cells (APCs) that function at the interface of innate and adaptive immune responses, constantly surveying the microenvironment and providing information to T cells. In contrast to macrophages which degrade antigens, DCs activity is biased towards antigen processing for presentation. DCs are widely distributed across different tissues, but their density is relatively low (Shortman, 2020). Different DC subtypes are responsible for the initiation, regulation of the immune response or for maintaining immune tolerance. Major DC subsets are categorized by their ontogeny into conventional DCs (cDCs) or plasmacytoid DCs (pDCs). Functionally, these subsets are characterized by their different ability to recognize molecular patterns, circulate through the body (pDCs) or to reside in thymus and lymphoid tissues (cDCs) and can be distinguished by marker expression and transcription factor set. cDCs are subcategorized into cDC1 or cDC2 types depending on their XCR1 and CD172 expression. A distinct subtype of DC—MoDCs (monocyte-derived DCs)—was shown to differentiate from monocytes during inflammation. A typical characteristic of all DC subtypes is their maturation stage. Immature DCs reside in barrier tissues and express low levels of co-stimulatory molecules. These cells demonstrate poor ability to activate T cells until they uptake an antigen. In a classical model, antigen uptake leads to DC maturation, migration to lymphoid organs, upregulation of MHC class I and class II and other membrane-associated and secreted molecules by means of which DCs drive activation and functional polarization of T cells. However, a concept of “steady-state condition” and “inflammatory condition” dichotomy (Boltjes and van Wijk, 2014) in case of DC maturation is complicated by the fact that DC still can mature in steady state to induce tolerance in peripheral Tregs (Iberg and Hawiger, 2020). Moreover, cDC1s provide constitutive expression of IL-12, promoting Th1 differentiation signaling even in the absence of antigens (Hilligan and Ronchese, 2020) and making Th1 response the ‘default-type’ response in contrast to Th2-response which requires potent antigenic signaling. Many tools have been applied to study DCs in vitro and in vivo, including FACS, single-cell RNAseq, culture with danger-associated and pathogen-associated molecular patterns, co-culture with T cells, genetic knockout (including Cre-based conditional knockout), DC subset depletion and various reporter visualization techniques. A substantial pool of studies has been focused on DC-like cells derived in vitro from blood monocytes in conditioned media, however, sophisticated methods are used to isolate rare DC populations from tissues, such as walkout method (induced migration of DC out of biopsied samples in culture) (Sun et al., 2020).

Phenotype

Each DC subset is characterized by its own set of markers but is lacking lineage markers (such as CD3, CD14, CD15, CD56, CD19 and CD20). DC phenotype differs between species, human DCs lack CD8 molecule while a significant subset of murine DCs expresses high levels of CD8 $\alpha\alpha$. However, murine CD8⁺ DCs express the chemokine receptor XCR1 which is also found on a population of human DC1s with similar characteristics (Guilliams et al., 2014). DC1 subset, in addition to XCR1, is also distinguished by the surface expression of CD11c, BTLA, CD141, CLEC9A, NECL2 and DEC-25. In nonlymphoid tissues cDC1s also express CD103 (Hilligan and Ronchese, 2020). DC2 subset is characterized by surface molecules CD1c, CD172a, DCIR2, CLEC10A, SIRP α , CD301b (MGL2), CD206, PDL2 and CD11b. SIRP α was shown to be a characteristic cDC2 marker, distinguishing this population from cDC1 in human bone marrow and blood (Hilligan and Ronchese, 2020). Two subsets of human blood cDC2s were identified based on the expression of CD32B (also CD5^{high}) or CD163 and CD36 (monocyte-like CD14⁺/CD5^{low} cells termed as DC3) adding to the complexity of DC nomenclature. Ironically, absence of strong subpopulation markers within cDC2 subset

highlights the high heterogeneity of these cells, since no marker can be used to distinguish one population from another while it is known that many subpopulations exist. Single-cell transcriptional studies have demonstrated high variability of cDC2s (Brown et al., 2019).

pDCs express B220, CD123, CD303, CD304, BST2 and Siglec-H (Iberg and Hawiger, 2020; Amon et al., 2020). The exact phenotype and transcriptional profile of each DC subset is governed by the state of development and activation and relies on microenvironmental conditions. E.g., lymphoid tissue-resident DCs express higher levels of H2-DMA and H2-DMab compared to lymph nodes migratory DCs reflecting resident cells ability to process antigens in contrast to mature cells (Hilligan and Ronchese, 2020).

MoDCs in mice express CD64, a monocyte/macrophage marker, upon inflammatory conditions. These cells also bear Ly6C, CD11c and CCR2 (Hilligan and Ronchese, 2020).

Langerhans cells (LCs) represent about one tenth of the epidermis cells in the skin are not DCs, however they resemble some DC properties and phenotypic features. Ontogeny studies and ability of LCs to proliferate in a differentiated state clearly indicate their macrophage origin. LCs can be identified by the expression of CD11c, CD32, CD45, FcεR1, CD1a, CD207 (langerin), CD324, CD326, HLA-DR and lack of XCR1 and CD103 expression (Deckers et al., 2018).

Tissue distribution

Differentiated DCs can be found in hematopoietic tissues and lymphoid organs, as well as in barrier tissues with a varying frequency. Spleen is highly populated with CD141+ cDC1s, bone marrow and blood and cord blood contain CD1c+ cDCs, while tonsils show the highest frequency of pDCs (Amon et al., 2020).

Lymphoid tissue-resident DCs are non-migratory cells that are initially seeded in spleen, lymph nodes or Peyer's patches and exist here on par with tissue-derived DCs. These DCs express low levels of CCR7 and MHC II and high levels of CD11c in steady state but upregulate CCR7 during maturation. cDC1 and cDC2 are positioned at separate regions inside lymphoid tissues due to differential expression of CXCR3 and CXCR1. Resident cDC2s are mostly localized in the proximity to subcapsular sinuses of lymph nodes where they sample soluble antigens arriving with the lymph flow. cDC1s reside in the paracortex where they uptake cell-associated antigens for subsequent cross-presentation in association with MHC class I molecules (Leon and Lund, 2019; Eisenbarth, 2019). Resident cDC1 and cDC2 also have distinct transcriptional profile in contrast to migrating cDC subpopulations in which transcriptome to a greater extent depends on the activation signals than on the ontogeny (Hilligan and Ronchese, 2020). Migratory DCs have a short lifespan and die by apoptosis in 2 days after migration as demonstrated for cDC2s (Tomura et al., 2014).

Human skin contains all three DC subsets and DC-like cells of monocyte origin in the dermis where DC density is highest in the superficial layers and decreases in deeper layers (Ronchese et al., 2020). Superficial DCs show high expression of fascin, an actin-binding protein responsible for cells motility. cDC1 population is underrepresented in the murine and human skin and DC2s are the most abundant. A population of CD301+ DCs inhabits a specific niche in the skin in perivascular areas where these DCs are able to transfer allergens from blood vessels to dermal mast cells, contributing to anaphylactic reactions (Ronchese et al., 2020).

Upon labeled antigen injection, cDC2s make up the majority of cells that reach draining lymph nodes. In mice, skin DCs also include additional cDC population lacking CD11b expression. Many of cDCs in the skin express chemokine receptor XCR1 (lymphotactin receptor/G-protein-coupled receptor 5) and produce chemokine CXCL10 thereby actively interacting with CD8+ T cells and NK cells, including cross-presentation to CD8+ T cells. A minor subpopulation of DCs, CD326+ cells also recruits neutrophils into infected skin via synthesis of VEGFα (Ronchese et al., 2020). CCR7 expression by the skin DCs of the skin allows them to migrate to lymphoid organs (Amon et al., 2020; Hilligan and Ronchese, 2020). While skin cornified layer is sampled by LCs, topically applied antigens can reach hair follicles where they are readily accessed by dermal cDC2s that provide tolerance to commensal microbiota in steady state but initiate IFNγ-mediated inflammatory response if the skin integrity is breached. Importantly, SKH1 hairless mice are unable to respond to epicutaneous OVA application (Tordesillas et al., 2018). Dermal DCs provide a pathway to airborne allergen sensitization, as skin application of house dust mite allergens resulted in antigen uptake by DC2s with consequent initiation of airway inflammation (Ronchese et al., 2020). Filaggrin deficiency which impairs skin barrier function may result in food allergy. This suggests an important role of skin DCs in the atopic march—a progression of allergic diseases from atopic eczema to food allergy, allergic rhinitis and asthma. A crosstalk between skin LCs and underlying cDCs allows the transfer of antigen-MHC class II complexes from LCs to more mobile cDCs. Notably, LCs, due to their proximity to commensal skin microbiota, have been proposed to be intrinsically tolerogenic which is supported by a series of experiments with LC depletion leading to Treg failure (Hilligan and Ronchese, 2020; Ronchese et al., 2020). However, upon proper environmental signals LCs excel in naïve T cell activation via cross-presentation pathway. Thus, skin commensals along with LCs and DCs constitute an immunoregulatory axis which is necessary to immune tolerance and immune protection in the skin.

DCs located in the lung tissues are presented by cDC1 and cDC2 populations with a variable expression of CD207. Human lungs are characterized by a relatively low proportion of cDC1. Lung cDC2s actively migrate due to the CCR7 expression and are distinguished by dynamically changing metabolic profile which reflects their ability to react rapidly to changing environmental cues in lung epithelial barriers (Amon et al., 2020; Hilligan and Ronchese, 2020).

Within the gut, distinct DC populations can be found in Peyer's patches (PP), mesenteric lymph nodes or lamina propria (LP) and lymphoid aggregates (Sun et al., 2020). DCs of intestinal LP are characterized by CCR9 expression. Intestinal cDC2s show

relatively high migratory capability which allows them to relocate into draining lymph nodes where they induce T cell responses, including cross-presentation. cDC2s also comprise a majority of DCs in small intestine LP, while colonic LP DCs are presented mostly by cDC1s. Correspondent ratios of migrating DC subsets is identified in lymph nodes that drain different sites along the gut. Diversity of gut DCs is extended by the lymphoid tissues aggregated along the intestine where cDC1s and pDCs dominate the DC population. In PPs, distribution of DC subtypes resembles that of lymph nodes with cDC2s localized in subepithelial dome (providing direct access to antigens) and cDC1s localized in T-cell regions in the deeper compartment, interfollicular zone (Sun et al., 2020). In contrast to lungs, intestines are densely populated with commensal microbiota and gut DCs are less motile and reactive in steady-state, thus maintaining microbiota-tolerant environment. Intestinal DCs project their dendrites into the intestinal lumen and also are able to obtain antigens via gap junctions indirectly, from macrophages (Hilligan and Ronchese, 2020). Alertness of mucosal DCs along alimentary tract may depend on quantity of commensals and pathobionts. DCs as central regulators of immune responses provide a balance between tolerance and inflammation and accompanying dynamic changes in microbiota composition. This can be described as an axis comprising microbiota, DCs, ILCs, T cells and IgA-producing B cells in a constant cross-talk with each other. Lymphotoxins α and β play crucial role in orchestrating of this axis because LT α or LT β ablation in ILCs results in reduction of IgA levels while LT β controls inducible nitric oxide synthase (iNOS) expression in DCs and impacts intestinal microbiota composition (Kruglov et al., 2013). Induction of oral tolerance among other factors relies on ILC3s that secrete GM-CSF, promoting intestinal cDC population to secrete retinoic acid (Sun et al., 2020).

In the oral cavity, sophisticated interactions between microbiota and immune cells are exemplified by bacteria *Porphyromonas gingivalis* which induce subinflammatory conditions readily converting to inflammation upon excessive growth of this bacteria (Meghil and Cutler, 2020).

Development

Steady-state DC half-lives is thought to be a few weeks, and senescent cells need to be replaced by the newcomers or by proliferating tissue-resident cells (Merad and Manz, 2009). Either way, a progenitor cell is needed to migrate into the tissue. Many insights into DC biology were obtained when the culture method for DC-like cells generation from blood monocytes or HSCs was proposed. The essence of this method was the addition of granulocyte/macrophage colony stimulating factor (GM-CSF) and IL-4 or TNF into culture media containing CD14+ monocytes or CD34+ HSCs (Romani et al., 1994; Sallusto and Lanzavecchia, 1994) to produce cells now referred to as MoDCs or LC-like cells (Luo and Dalod, 2020). Later, DC studies were expanded through identification of several mutations that affected DC development in human patients. Further discovery of many DC subsets complicated the knowledge about DC development. First experiments demonstrated that both CD8+ and CD8- DCs can be produced from either oligopotent common lymphoid (CLP) or myeloid (CMP) progenitors, having multipotent CD34+ hematopoietic stem cells (HSCs) as initial founders (Shortman, 2020). Moreover, there is some experimental evidence that cDC1 and other DC subtypes commitment occurs in early hematopoiesis independently of the lymphoid and myeloid lineages segregation (Luo and Dalod, 2020; Naik, 2020). However, it is largely accepted now that the majority of DCs derive from myeloid precursors. The last progenitor cell from which all DC subsets can be differentiated was described as granulocyte/macrophage progenitor (GMP) expressing CD34 + CD38 + Lin - CD10 + CD45RA+ phenotype in the bone marrow (Lee et al., 2015). Further development of DCs is associated with CD34 downregulation, since a circulating lineage - HLA-DR + CD100 + CD34^{int} cDC progenitor was identified which was able to proliferate and give rise to cDC1 and cDC2 (Amon et al., 2020). Thus, in contrast to cultured DC-like cells, late cDCs progenitors in vivo do not belong to monocytes. Instead, bone marrow precursors seed peripheral lymphoid organs via bloodstream to give rise for cDC1 and cDC2 populations. A commitment to cDC1 or cDC2 seems to take place in bone marrow before precursors enter the circulation (Schlitzer et al., 2015), but some data support an opinion that uncommitted pre-cDCs can be found in bone marrow and blood (Amon et al., 2020).

A series of experiments dedicated to thymic DCs produced ambiguous results indicating that while major source of thymic DCs are bloodstream precursors, there may exist a subset of DCs that has an intrathymic origin. Genetic and pharmacological manipulation of the transcription factors shed light onto identity of distinct DC types. As mentioned above, studies of mutations in human cells also provided significant data on the requirements of DC differentiation. E.g., *TCF4* loss in patients with Pitt-Hopkins syndrome results in decreased pDC differentiation, as well as *IKZF1* mutations. IRF8 deficiency affects development of most DC subtypes (Luo and Dalod, 2020).

In the bone marrow, the fate of early DC precursors (or common DC precursors, CDPs) is largely dependent on the cytokine Fms-like tyrosine kinase 3 ligand (FLT3L). FLT3L is structurally homologous to stem cell factor (SCF) and colony stimulating factor 1 (CSF-1) and regulates proliferation of early hematopoietic cells. CD135, the FLT3L receptor, is downregulated in circulating progenitors, as well as CD116 (GM-CSFR) (Amon et al., 2020). However, FLT3L has been shown to stimulate the DC proliferation in lymphoid tissues in response to inflammatory cues. Experimental administration of FLT3L resulted in the increase of circulating cDC1s and cDC2s that may represent a part so-called "emergency myelopoiesis" in response to systemically disseminated microbial pathogens. This leaves uncertainty about cells that originate the emergency response: experimental evidence suggests that, e.g., bone marrow epithelial cells or tissue macrophages can be the source of myelopoietic factors needed for the proliferation of DC progenitors (Bieber and Autenrieth, 2020). Common transcriptional factor that differentiates cDCs from pDCs is zinc finger transcription factor zBTB46 (Hilligan and Ronchese, 2020). The development of DC1s is directed by the transcription factors Interferon regulatory factor (IRF8), Id2 and Basic Leucine Zipper ATF-Like Transcription Factor 3 (BATF3), while DC2s development

is directed by Zeb2, IRF4, Klf4 and Notch2 (Amon et al., 2020; Hilligan and Ronchese, 2020). IRF4 is also crucial for the development of MoDCs, which was demonstrated in IRF4 knockout cells (Briseno et al., 2016).

TLR ligands may affect DC development. In mice, lymphoid progenitors develop into DCs upon binding with TLR2/TLR4 ligand, while bone marrow CD34+ hematopoietic stem cells give rise to DCs in presence of TLR1/TLR2, TLR7/8 and Nod2 ligands. More differentiated DC progenitors develop into distinct DC populations upon stimulation with LPS, CpG, *Candida albicans* and a range of viruses and parasites (Bieber and Autenrieth, 2020). This stimulation also increases CCR7 expression to promote DC migration into inflammatory sites. However, DC development can as well be impaired by infectious pathogens that stimulate monoopoiesis at the expense of DC generation.

Some functions of cDCs that may attribute them into one or another functional subset, develop in the periphery where they are locally shaped by tissue microenvironment (Eisenbarth, 2019). A representative example is strong cross-presentation capacity classically attributed to cDC1s which is induced by GM-CSF and TLR ligands in lymphoid tissues (Shortman, 2020). However, cross-presentation was also demonstrated in cDC2s and pDCs, especially in the presence of immune complexes (Amon et al., 2020). Mesenteric lymph node (MLN) stromal cells provide essential signals that modulate DC functions in a manner that ensures Treg induction (Pezoldt et al., 2018).

Mouse studies on the origin of pDCs mostly point to their development solely from a lymphoid progenitor common with B cells, in contrast to cDCs. It is no surprise then that many pDCs resemble some features of B cells, including RAG-1 expression and D-J rearrangements in IgH genes (Luo and Dalod, 2020; Rodrigues and Tussiwand, 2020). Murine bone marrow cells were shown to differentiate into pDCs in the presence of GM-CSF and TLR4/TLR9 ligands, and transcription program for DC development involves IRF8 and TCF4 (Bieber and Autenrieth, 2020; Ah Kioon et al., 2018). For human pDCs, their origins still remain to be elucidated. pDC development largely relies on transcription factor E2-2 (TCF4) and interferon regulatory factor 7 (IRF7) (Amon et al., 2020; Hilligan and Ronchese, 2020). However, the same E2-2 in chronic viral infections impairs pDC generation leading to exhaustion of pDC responses (Macal et al., 2018).

In addition to classical method of MoDC generation, many other protocols for generation of DCs have been introduced later on. They include cDC1, cDC2 and pDC differentiation from HSCs or iPSCs, trans-differentiation of fibroblasts into cDC1s and immortalization of primary human DCs. Alignment of these cells to their counterparts in human tissues provided valuable knowledge on DC ontogeny, differentiation and function in vivo. Novel technical advances, e.g., genetic barcoding of HSCs offered additional insights into DC developmental pathways. Barcoding involves labeling of HSCs with lentivirus stock containing a library of DNA barcodes that integrate into single cell genomes. During cell division, barcodes are inherited in the offspring cells. PCR analysis of progeny points to the ancestor cell (Naik, 2020) (Fig. 1).

Fig. 1 A simplified scheme of dendritic cells ontogeny, phenotype and secretory profile.

Activation and function of DCs in infection

DCs are crucial for the activation of T cells and maintaining central and peripheral tolerance as well as for providing essential regulatory signals during the immune response. Exact function and activity spectrum are not hardwired, but depend on the subset, location and time, reflecting high adaptability of DCs in changing microenvironment. A functional plasticity in DC subsets may also take place, since intermediate, or transitional types of DCs, such as AXL, SIGLEC1 and SIGLEC6-expressing DCs of myeloid origin were recently characterized. These cells, nonproliferating and failing to produce type I IFNs were designed as AS DCs, exhibiting both pDC and cDC2 properties (Amon et al., 2020; Ah Kioon et al., 2018).

DCs sample their environment at barrier tissues by extending their dendrites through tight junctions of adjacent epithelial cells, gaining access to a variety of antigens. These antigens are further internalized via phagocytosis, receptor-mediated endocytosis or micropinocytosis (Hilligan and Ronchese, 2020). The priming of immune responses by DCs initiates with signaling from pattern recognition receptors (PRRs) indicating the presence of infection, inflammation, or the environmental cues at their patrolling sites. These PRRs include TLRs 1–10 (in humans), C-type lectin receptors (DC-SIGN, SIGNR1, LSECtin, MCL, Langerin, MR and DEC205), Nod-like receptors, RIG-I-like receptors and formyl peptide receptors (FPRs). The signals provide changes in DC motility, metabolism and secretory activity that accompany DC transition from immature to mature state. Depending on the type of the environmental signals, this maturation may lead to the development of inflammatory or tolerogenic DC phenotype, both showing CCR7 expression that allows migration into the draining lymph nodes.

Inflammatory DC maturation occurs upon contact with pathogen-associated antigens or damage-associated molecular patterns derived from necrotic cells. The latter bind to CLEC9A (DNCR-1) receptor on DCs that activates maturation pathway which involves up-regulation of costimulatory molecules (CD80, CD86), maturation markers (CD83), and antigen presenting molecules (MHC class I and II). Migratory capability is another hallmark of maturation which is accompanied by upregulation of CCR7, as mentioned above (Iberg and Hawiger, 2020).

Peptide-MHC complexes on the DC surface interact with antigen-specific TCRs on T cells. Type of presentation (MHC I or MHC II), strength and duration of co-stimulatory signaling and cytokine signaling milieu determine the type of T cell response and the fate of naïve CD4⁺ T cells. Intracellular pathogens are efficiently eliminated largely due to the cross-presentation capability of cDC1 cells, while cDC2s promote Th2 and Th17 responses directed against extracellular pathogens (Amon et al., 2020). Migrating pre-DC1s were shown to express CXCR3 which respond to IFN-inducible CXCL9/10/11 that support their relocation in response to intracellular pathogens (Hilligan and Ronchese, 2020). Mechanisms of antigen processing and presentation are described in the correspondent section (“see ‘Antigen processing and presentation’”). In addition to classic antigen presentation and cross-presentation, DCs are able to produce exosomes (Dex—DC-derived exosomes) containing peptide-MHC complexes that present antigens to CD4⁺ and CD8⁺ T cells. Moreover, Dex provide cross-dressing process where APCs internalize Dex with the subsequent antigen reprocessing and presentation. Upon Dex internalization by tumor cells, the latter may become more immunogenic (Wang et al., 2020).

Upon maturation, DCs of different subtypes may produce distinct effects in T cells, mostly via differential cytokine induction. DC secretome is dependent on the engaged spectrum of PRRs. E.g., IL-12 expression is enhanced by TLR3, TLR8 and TLR9 signaling in cDC1s that secrete high levels of IL-12 and type III interferons to drive Th1 response. CD5^{high} cDC2 produce large quantities of TNF α , IL-6, IL-10, and IL-23, which makes them able to efficiently prime Th2, Th17. Th17 differentiation is guided by IL-6 and TGF β secreted by cDC2s upon ligation of TLR2 and Dectin-1 by fungal glucans. CD5^{low} cDC2 stimulates Th1 CD4⁺ T cell differentiation and are also able to prime Th2 and Th17 in some experiments (Amon et al., 2020). Of note, Th2 differentiation requires lack of IL-12 and presence of IL-4, but there is little evidence that DCs provide initial source of IL-4. Both cDC subsets are able to induce Tregs via TGF β secretion if an antigen is encountered in non-inflammatory microenvironment. DCs bear α v β 8 integrin which serves to convert inactive TGF β into an active molecule, and loss of α v β 8 integrin in DCs results in autoimmunity as well as loss of TSLP, which is exemplified by MLN DCs (Travis et al., 2007; Spadoni et al., 2012). MoDCs stimulate Th1 cells by producing IL-12 (Hilligan and Ronchese, 2020). DCs have a critical role in the Tfh subset differentiation which is essential for germinal center formation and affinity maturation. Besides B cell signaling, Tfh differentiation involves cDC2-derived IL-6 and ICOS co-stimulation as well as type I IFNs, IL-27, IL-1 β and TNFR superfamily member OX40 (Hilligan and Ronchese, 2020). Moreover, pDCs have been shown to induce plasma cell differentiation even in the absence of helper T cells (Ah Kioon et al., 2018).

Neural regulation may play a role in DC functions as it has been shown that cutaneous neurons induce IL-23 synthesis in DCs by the neuropeptide CGRP (calcitonin gene related peptide) and neuron stimulation can drive IL-23-mediated skin inflammation in the absence of pathogen (Cohen et al., 2019).

DCs and their progenitors provide an important to the idea of “trained immunity” which advocated imprinting of DC progenitors towards innate inflammatory responses somewhat representing immunological memory but, of course, without the specificity attributed to adaptive immunity. For example, BCG administration results in the enhanced proliferation of myeloid lineage during second antigen encounter and provides heterologous protection against a broad range of pathogens, including viruses (Cirovic et al., 2020). Epigenetic landscape profiling using mass-cytometry (EpiTOF) have shown changes in histone modifications of DCs which are possibly essential to DC reprogramming by vaccines (Kar and Joosten, 2020). Intriguingly, several observation studies have proposed that countries with high BCG vaccination coverage had fewer COVID-19 cases and associated deaths cause by SARS-CoV-2 that emerged in 2020 (Kleen et al., 2020). “Trained immunity” concept can provide some cues about the role of DCs in this phenomenon.

pDCs are involved in the antiviral immune response associated with rapid production of type I interferons and tolerance. However, the presence of CD4, CCR5 and CXCR4, as well as DC-SIGN (Dendritic Cell-Specific Intercellular adhesion molecule-3-Grabbing Non-integrin) turns them into targets for HIV infection which are able to pass on the virus to the T cells (Evans et al.,

2011). While pDCs are easily infected by viruses this may have beneficial effects in some cases where viruses, such as VSV, need to be replicate-active to induce type I IFN response. Cross-talk of infected and uninfected pDCs produces effective antiviral response (Ah Kioon et al., 2018).

DCs and cancer

cDC functions are not limited by anti-infectious or tolerogenic responses. Key role of DCs an anti-tumor response has been demonstrated in multiple studies in mouse models, including melanoma and sarcoma. BATF3 knockout in mice results in the loss of ability to reject even highly immunogenic tumors or to respond to checkpoint inhibitors while restoring of cDC pool increases response to immunotherapy against tumor (Gardner et al., 2020). Other experimental data support the indispensable role of cDC1s in the eliciting of anti-tumor CD8+ T cell response. Lack of CCR7 in DCs results in insufficient recruitment of T cells into the sites of neoplasia, and CXCL9/CXCL10 production by cDCs is essential for the tumor infiltration by CTLs, while the loss of cross-presentation function causes a breakdown in tumor rejection. It's interesting that DC recruitment into the tumor relies on other innate player, NK cells which produce Flt3 ligand, CCL5 and XCL1, facilitating DC migration. Synthesis of IL-12 in return promotes IFN γ production by NK cells. Clinical findings proved that the presence of cDC1s in human tumors is also associated with better prognosis. Additionally, there is some experimental evidence for the requirement of cDC2s in tumor control provided by CD4+ T cell response. The role of pDCs and MoDCs in tumors is less defined, while pDC presence in tumors correlated with poor or better prognosis in different settings (Gardner et al., 2020; Del Prete et al., 2020).

DC failure and malfunction

Pathogens have evolved many strategies of immune evasion including induction of DC death. This is particularly the case with regard to systemic infection and sepsis. Many models of systemic infection provide experimental evidence of DC failure both in terms of quantity and function. Infection with *Salmonella typhimurium*, polymicrobial sepsis and parasite invasion were shown to result in attrition of tissue DCs via MyD88-mediated apoptosis and altered cytokine production by DCs (Bieber and Autenrieth, 2020). Consequential immunosuppression leads to secondary infections due to DC and T cell anergy. Similarly, influenza infection in mice have impaired lung DC population thereby increasing susceptibility to secondary infection (Beshara et al., 2018). SARS-CoV-2 was also shown to affect DC maturation and to induce TRAIL-mediated apoptosis. It was proposed that delayed innate immune response in early COVID-19 infection sequenced by excessive inflammatory response is accountable for the severe clinical course, pointing to the possible role of DCs in the course of disease (Kleen et al., 2020). Studies of tumor microenvironment show that tumor-associated cDC2s can be reprogrammed to obtain immunosuppressive functions, adding to detrimental effects of immunosuppressive tumor-associated macrophages (TAMs), myeloid-derived suppressor cells (MDSCs) and Tregs (Luo and Dalod, 2020; Maier et al., 2020). DCs themselves are also a subject of tumor transformation, and dendritic cell leukemia is recognized as a distinct hematopoietic neoplasm showing characteristic immunophenotype of pDCs with CD123 and CD303 (CLEC4E) expression (Tsagarakis and Paterakis, 2020).

pDCs have been shown to contribute to autoimmune diseases pathogenesis, including systemic lupus erythematosus (SLE), systemic sclerosis (SSc), type I diabetes and psoriasis. TLR8-induced secretion of CXCL4 and IFN α by pDCs infiltrating the skin in SSc promotes inflammation and fibrosis. In SLE, pDCs react to immune complexes and contribute to disease activity via IFN α secretion. Skin cDCs in psoriasis cross-talk with PGE2-producing fibroblasts and secrete IL-23, TNF α and IL-1 β , that contribute to Th17-mediated inflammation. In graft-versus-host disease (GVHD) pDCs prime alloreactive T cells, however a number of studies have shown protective functions, including Treg induction (Ah Kioon et al., 2018; Hilligan and Ronchese, 2020).

Tolerogenic DCs

Experiments with a range of physiological and chemical signals provided evidence for the tolerogenic DC functions and revealed that cDC1s and cDC2s are mutually redundant in ensuring tolerance via Treg induction (Sun et al., 2020). These functions, in turn, ensure homeostasis at the skin and mucosa, maintaining proper responses to commensal microorganisms and environmental non-pathogenic antigens (Iberg and Hawiger, 2020). E.g., *Mycobacterium vaccae*, a non-pathogenic soil bacterium, abundant in rural areas with livestock farming, provides tolerogenic DC response and exerts anti-allergic properties. Intriguingly, mode of *M. vaccae* lysate administration seems to have different consequences. Epicutaneous lysate application was shown to be feasibly more efficient than heat-killed *M. vaccae* subcutaneous injections, probably owing to LC stimulation (Strygin et al., 2020). This phenomenon is in line with the hygiene hypothesis, or "old friends hypothesis" of allergy development partly confirmed by lower allergy prevalence in livestock farming areas. The signaling pathways that drive tolerogenic response in DCs still remain to be elucidated.

Mechanisms of peripheral tolerance induction involve anergy, T cell deletion and pTreg development (Iberg and Hawiger, 2020). Tolerogenic DCs rely on the synthesis of anti-inflammatory cytokines, including IL-10 and TGF- β , but other soluble factors, such as chemokine CCL3, vitamin D3 and retinoic acid, also play a role in the induction of pTreg. Tolerogenic cDC1s residing in lymphoid organs express immunomodulatory molecules B7h, BTLA, PD-L1, CD80/86 which induce formation of pTregs upon

antigen presentation in steady state and negatively regulate other CD4⁺ T cell subsets (Hilligan and Ronchese, 2020). Antigens used in this presentation derive from apoptotic cells which are ingested via scavenger receptor CD36 which is highly expressed on cDC1. These antigens can as well be displayed via the cross-presentation pathway. Tolerogenic DCs in skin, intestines and airways are in constant contact with a range of pathogens and commensal microbiota and exert their tolerogenic functions in a subinflammatory manner being activated via pattern recognition receptors (PRRs). Since same PRRs may promote an immunogenic response, the exact pathway highly depends on different microenvironmental signals, including IL-10. Moreover, specific associations of activated TLRs may result in different responses. E.g., *Yersinia pestis* antigen LcrV binding to TLR6/TLR2 heterodimer produces tolerogenic response, while binding to TLR1/TLR2 heterodimer leads to an immunogenic response (Depaolo et al., 2008).

Food-derived antigens mostly comprise harmless antigens that require tolerogenic response referred to as oral tolerance. Intestinal DCs provide a non-redundant link ensuring oral tolerance induction which normally prevents hypersensitivity and inflammatory responses. Intestinal DCs express G-protein-coupled receptors (e.g., GPR109a) which serve as ligands for short-chain fatty acids (SCFAs) and other substances inducing tolerogenic pathways (Iberg and Hawiger, 2020). Other factors that promote induction of tolerogenic DCs include ligands of aryl hydrocarbon receptor (AHR) and vitamin D receptor (VDR) as well as vasoactive intestinal peptide (VIP). Of note, cDC2/cDC1 ratio matches vitamin A local concentrations and *Aldh1a2* is highly expressed in proximal intestines where cytokine milieu is also biased towards anti-inflammatory cytokines (Esterhazy et al., 2019). Vitamin A-derived retinoic acid is probably the most distinguished dietary factor that governs gut DC functions. Gut DCs, like many other intestinal cells, express retinaldehyde dehydrogenase (RALDH) encoded by *Aldh1a2* gene (encoding retinaldehyde dehydrogenase 2 or RALDH2), an enzyme involved in retinoic acid production. This enzyme converts vitamin A into retinoic acid that exerts multiple immunomodulatory functions, including cDC2 development with ability to induce Tregs and provide their migration into the LP via CCR9 and FoxP3 induction (Sun et al., 2020). Notably, *Aldh1a2* is upregulated in small intestine DCs, where strong Treg induction was shown (Hilligan and Ronchese, 2020). A variety of other food components also influences DC functions, including SCFAs (particularly, butyrate) produced by anaerobic fermentation of dietary fibers. Polysaccharide A and zymosan that derive from gut microbiota promote tolerogenic DC responses as well as mucin-2 (host mucus component) (Sun et al., 2020).

Clinical utility of DC targeting

Obviously, harnessing of tolerogenic DCs represents promising therapeutic modalities for the treatment of allergy, autoimmune diseases, cancer, and in transplantology. However, clinical studies performed over the last two decades mostly focused on treating cancer and viral infections.

The ability of pDCs to produce high levels of type I IFNs made them most studied human DC subset since these cells offered promising therapeutic applications, namely in HIV infection. Recently, a human monoclonal antibody to type I IFN receptor subunit 1, anifrolumab, have demonstrated significant effectiveness in Phase III trial in SLE patients (Morand et al., 2020). Many studies have backed targeting cDC1s or cells harboring cDC1-like properties for treating cancer or infections by intracellular pathogens. Many preclinical and clinical trials involved DCs derived from monocytes for adoptive cell therapy of viral infections or cancer. Viral antigen-pulsed MoDCs were used recently for enhancing antiviral response in HIV-infected patients (Luo and Dalod, 2020). However, MoDCs fail to efficiently migrate into lymphoid organs. Moreover, restriction of good manufacturing practice (GMP) to MoDCs as the only subset that can be produced in large quantities did not contribute to successful treatments. This partly explains why utilizing DCs for antiviral and anticancer treatment have not reached success as expected. The only approved vaccine that utilizes exogenous expansion of DCs loaded with tumor lysate is sipuleucel-T that shows limited clinical effectiveness. Besides adoptive DC therapies, other approaches seek to improve DC functions in vivo (particularly by TLR agonists) or blocking of inhibitory signals (Gardner et al., 2020). Tumor antigen presentation may be facilitated by fusing tumor antigens to antibodies that bind DC (e.g., anti-CLEC9A, anti-DC-SIGN). One of the targets for these fusion proteins is DEC205 which seems controversial because targeting of DEC205 with OVA-coupled antibody was shown to induce tolerogenic response. This demonstrates complexity of DC-based approaches and the need for a deeper understanding of proper DC engagement, including subtype, timing and location (Lamendour et al., 2020; Wculek et al., 2020; Del Prete et al., 2020). Recently, efforts have been made to engage DC cross-presentation process to facilitate antiviral CD8⁺ T cell generation by vaccines. However, long-term and efficient T cell induction remains challenging; moreover, cross-presentation is a slow process and requires active pathogen replication.

Adoptive DC generation is also under development in solid organ transplantation studies. Potent immunosuppressive capabilities of DCs have been shown in animal experiments where regulatory DCs were able to increase transplant survival time (Luo and Dalod, 2020).

Beyond their multiple specializations, DC types differ in susceptibilities to infection by intracellular pathogens or to hijacking of their immunoregulatory activities by microbes or tumor cells. Targeting of DCs for vaccination or immunotherapy purposes should take into account that the right DC type should be used to avoid unwanted sequela in patients while providing beneficial effects.

Introduction

Natural killer (NK) cells are innate cytotoxic lymphocytes that were first described in the 1970s as a unique population of non-T and non-B cells that spontaneously lysed tumor cells (Kiessling et al., 1975). Today we know that NK cells are complex, professional killer cells that are indispensable for the defense against microbial pathogens (particularly viruses), are involved in tumor surveillance, and have a role in various non-infectious human diseases (Orange and Ballas, 2006). NK cells are functionally unique because their immunological properties are not dependent on prior antigen sensitization—they lack antigen-specific T cell and B cell receptors. They recognize infected or damaged cells using a diverse set of germline-encoded receptors. Integration of the various contact-mediated and cytokine-induced signals activate kill pathways to eliminate the infected or damaged cells. Aberrations in these pathways lead to increased susceptibility to viral infection, malignancy, or autoimmune/inflammatory disorders. In the following chapter, we will review the basic biology of NK cells, their role in infection control and other human diseases, and the genetic defects that contribute to primary NK cell deficiencies (NKD).

NK cell development

NK cells arise in the bone marrow (BM) and differentiate in secondary lymphoid tissues (SLT) (Abel et al., 2018). Studies on human NK cell maturation have demonstrated six distinct stages of development. Briefly, self-renewing CD34⁺ hematopoietic stem cells (HSC) in the bone marrow produce oligopotent common lymphoid progenitor cells (CLPs). CLPs differentiate into pre-T/pre-NK cell progenitor (pre-NKP) cells, Pro-B cells, or innate lymphoid cells (ILCs). Pre-NKP cells (Stage 1 NK cells) express CD244 which is an immunoregulatory transmembrane receptor in the signaling lymphocyte activation molecule (SLAM) family. CD244 mediates both activating and inhibitory signaling in NK cells and remains present throughout all subsequent stages. Pre-NKP cells differentiate into Stage 2a/2b NKP cells which express c-Kit (CD117) and IL-1R1. Expression of IL-15R β -chain (CD122) and IL-15R α during Stage 2b irreversibly commits the cells to the NK lineage and is important for NK cell survival. Stage 3 NK cells are defined by high levels of IL-1R1 and start to express activating receptors (NKP45, NKP30, NKG2D, and NK1.1, discussed later in this chapter). When the expression of these activation receptors reaches maximal levels, the Stage 3 cells mature to Stage 4a and 4b found

in peripheral blood. Another defining feature of Stage 4 NK cells is the very high expression of CD56 (CD56^{bright}) and the absence of the activating receptors FcγRIIIA (CD16) and KIR (CD158). CD56, also known as neural cell adhesion molecule-1, is not believed to have any known function. The function of CD16 and KIR will be discussed later. CD56^{bright} NK cells are potent cytokine-induced, cytokine-producing pro-inflammatory cells with robust anti-tumor activity. CD56^{bright} NK cells produce TNFα, IL-5, and IL-13. Stage 4 NK cells differentiate into Stage 5 NK cells by downregulating CD56 expression (CD56^{dim}) with concomitant increased expression of the activating receptors CD16 and KIR. These CD56^{dim} cells have a mostly cytotoxic effector function (granule and antibody-mediated cytotoxicity) but can also produce cytokines. Together, Stage 4 and Stage 5 NK cells make up the majority of NK cells in the peripheral blood. CD56^{bright} cells are predominantly found in secondary lymphoid tissues with only 5–10% present in the blood. In contrast, CD56^{dim} cells make up >90% of NK cells in peripheral blood circulation. Finally, terminally differentiated (Stage 6) NK have high levels of NKG2C (CD159c) and CD57 and have “memory-like” features which allow them to recognize antigens (Pahl et al., 2018; Newhook et al., 2017; Cerwenka and Lanier, 2016).

NK cells are found in several immune compartments (primary and secondary lymphoid tissue) and non-lymphoid tissue (e.g., skin, liver, and uterus) (Freud et al., 2014). In the peripheral blood of healthy individuals, NK cells make up 3–20% of the mononuclear cell population (Mace and Orange, 2016; Angelo et al., 2015; Shearer et al., 2003) and total levels are affected by age, infection, and conditions that alter the cellular milieu (Mahapatra et al., 2017; Brady et al., 2010; Strauss-Albee et al., 2015). Additionally, NK cells have a half-life of about 2 weeks and can achieve 16 doublings in vitro before becoming senescent (Stringaris, 2017; Zhang et al., 2007; Shimasaki, 2020).

NK cell signaling

The effector function of NK cells depends on (1) distinguishing abnormal cells from normal cells, (2) mediating activating and inhibitory signaling pathways, (3) inducing an effector response via cytolytic proteins and soluble cytokines, and (4) terminating effector function (for comprehensive review, see Ref. Mace et al., 2014).

NK cells express multiple classes of receptors that are critical for chemotaxis, cellular adhesion, and initiating activating or inhibitory signals. Under homeostatic conditions, inhibitory pathways dominate, and the NK cells remain in a “ready and waiting state”. When the NK cells encounter “aberrant” cells with high concentration of activating ligands and reduced expression of inhibitory ligands, this overrides the inhibitory signals and promotes killing of the aberrant cells. Additionally, activated NK cells secrete cytokines and enhance recruitment and activation of accessory immune cells. As such, NK cells serve as a bridge between innate and adaptive immune responses.

Activating receptors

NK cell-mediated cytotoxicity requires signaling via activation receptors which include natural cytotoxicity receptors (NCRs), killer immunoglobulin-like receptors (KIR), NKG2D, and CD16 which will be discussed here (Chan et al., 2014). Other activating receptors including LFA-1, CD27, DNAM-1, CD2, IFNα/βR, IFNγR, IL-2Rα, IL-12Rβ, and IL-15Rβ are reviewed elsewhere (Orange and Ballas, 2006; Watzl and Long, 2010).

Natural cytotoxicity receptors (NCRs) are type I transmembrane (TM) proteins with Ig-like domains on the extracellular surface of NK cells. NCRs interact with multiple pathogen- or host-encoded ligands (e.g., influenza hemagglutinin, *Plasmodium* EMP-1; for comprehensive review, see Ref. Barrow et al., 2019). Nkp30, Nkp44, and Nkp46 are the best characterized human NCRs (Barrow et al., 2019). Nkp30 and Nkp46 are constitutively present on the surface of NK cells, while Nkp44 is expressed upon IL-2 mediated activation of the NK cells. Engagement of ligands with the NCR induces conformational changes that expose positively charged amino acid residues (arginine or lysine) in the transmembrane (TM) domain of the NCRs. These residues form salt bridges with corresponding residues on intracellular adaptor proteins (DAP10, CD3ζ, FcγR) that contain ITAMs, or immunoreceptor tyrosine-based activating motifs (Vivier, 2004). In general, intracellular cytoplasmic domain of the NCRs lack catalytic capacity and, hence, all signal transduction through NCRs must occur through adaptor proteins. The ITAM motif in this covalently-linked receptor-adaptor protein complex is then phosphorylated by Src family of tyrosine kinases (Src, Lyn, Lck) which leads to the recruitment and phosphorylation of Syk and Zap70 tyrosine kinases. This activates multiple signaling cascades including the phosphatidylinositol-3-OH kinase (PI3K), mitogen-activated protein kinase (MAPK), and extracellular signal-regulated kinase (ERK) pathways. The effector function of NK cells is mediated by activation of these different pathways. The ultimate effect is cytoskeletal rearrangements that release cytotoxic granules and activation of various cytokine/chemokine genes.

Killer immunoglobulin-like receptors (KIR; CD158) are an important class of receptors that are either activating or inhibitory. There are >13 KIR genes and although there is no KIR gene rearrangement, there is a very high level of diversity in KIR proteins derived from differences in KIR gene copy number variation and allelic polymorphism (Pende et al., 2019). The nomenclature of KIR genes is based on number of extracellular Ig domains (e.g., KIR3D has 3 Ig domains). Their functionality is determined by whether they have cytoplasmic ITIM domain, or immunoreceptor tyrosine-based inhibitor motifs. If an ITIM domain is present, the KIR protein nomenclature includes the label “L” (“long” domain); in the absence of an ITIM domain, it is labeled with “S” (“short” domain). KIR proteins recognize both classical and non-classical MHC Class I receptors (HLA-A/B/C or HLA-E, respectively). This interaction is crucial for preventing NK cell-mediated lysis of normal host cells (Pende et al., 2019). Importantly, loss of MHC class I is not sufficient enough to activate NK cells which require ligand interaction with activating receptors. There are few known

activating KIRs (aKIR) of which KIR2DS1 is the best characterized (Pende et al., 2019). KIR2DS1 has been demonstrated to play a role in viral and tumor recognition (Naiyer et al., 2017; Thiruchelvam-Kyle et al., 2017). Like NCRs, aKIR do not have ITAM domains and require that signal transduction occurs through adaptor proteins (e.g., KARAP/DAP12).

CD16a, or FcγRIIIa, is the low-affinity transmembrane protein receptor for IgG and is important for NK cell antibody-mediated cellular cytotoxicity (ADCC) discussed below. It co-localizes with CD3ζ and FcεRI on the surface of NK cells. Signaling is mediated via the classical ITAM pathway that leads to PI3K and PLCγ activation. Unlike other ITAM-dependent activating receptors, activation via CD16 alone is sufficient to activate NK cell cytotoxicity and secretion of cytokines including TNFα, IL-2, IL-3, and IL-4 (Bryceson et al., 2009). Mutations in CD16 cause functional NK cell deficiency (NKD), which is discussed later.

Natural-killer group 2, member D, or NKG2D, receptors are C-type lectin-like type II transmembrane proteins expressed on NK, NKT, and CD8 T cells. Endogenous ligands for NKG2D include major histocompatibility complex class I-related chain A and B proteins (MIC-A/B) and ULBP, which are highly expressed in malignant cells including melanoma, leukemia, and neuroblastoma (Paul and Lal, 2017; Pende et al., 2002). Signaling through NKG2D promotes the polarized release of lytic granules to kill the diseased cells. Expression of NKG2D is upregulated by TNFα, IL-1, IL-7, IL-12, IL-15, and IL-18 and downregulated by IFNγ and TGFβ (Paul and Lal, 2017).

Inhibitory receptors

Under normal, physiologic conditions, NK cells activity is restrained. This is crucial for establishing NK cell tolerance to self and is the basis for the “missing self” hypothesis (Ljunggren and Karre, 1990). Briefly, cells expressing “self-molecules” such as MHC class I glycoproteins prevent NK cell activation and subsequent target destruction. However, cytotoxic stress (induced by viral infection or malignancy) can downregulate the expression of MHC-I. Along with other activating signals, this shifts NK cell signaling toward an activating phenotype that kills infected cells while generally sparing autologous, healthy cells.

NK cell inhibitory receptors can be categorized as immunoglobulin-like or lectin-like. Immunoglobulin-like receptors include the KIR family, leukocyte Ig-like (LIR), and Ig-like transcripts (ILT). Separately, lectin-like receptors include NKG2A/B and KLRG1. KIR heterodimers form receptor-ligand interactions with Class-I MHC molecules (HLA-A, -B, and -C) expressed on healthy host cells. Heterodimeric CD94/NKG2A receptor binds to non-classical MHC-molecules (HLA-E). Other inhibitory signaling receptors include TIGIT, CD96, NKR1A. In spite of their structural differences, all NK cell inhibitory receptors have conserved intracytoplasmic ITIM motifs. Negative regulation via ITIM-containing receptors starts with ligand-receptor engagement which induces conformational changes that allows the inhibitory receptor to co-aggregate with activating receptors (FcγRIIIa or FcεR) (Vivier, 2004; Daëron et al., 2008). Src-family tyrosine kinases on the activating receptor phosphorylate the ITIM region (consensus sequence S/I/V/LxYxxL/V) which then recruits phosphotyrosine phosphatases (SHP-1 and SHP-2) and inositol phosphatases (SHIP). These phosphatases dephosphorylate both upstream and downstream signaling molecules in the competing activation pathways that are involved in the clustering and phosphorylation of activation receptors—hence, inhibition dominates (Vivier, 2004). NKG2A has emerged as a reasonable drug target for cancer immunotherapy since inhibition of the receptor can restore NK cell and NK T cells and promotes potent anti-tumor activity in preclinical trials (Creelan and Antonia, 2019).

NK cell effector pathways

NK cells have several non-mutually exclusive mechanisms of function: granule-dependent cytotoxicity, cytokine/chemokine-induced cell signaling, and antibody-dependent cellular cytotoxicity. The specific molecular steps involved in NK cell cytotoxicity are reviewed by Mace et al. (Mace et al., 2014).

Granule-dependent cytotoxicity

NK cells produce numerous specialized membrane-bound granules that contain lysosomal enzymes (cathepsins and hydrolases), lytic proteins (perforin, granzysin, and anti-microbial peptide) and pro-apoptotic molecules (granzymes, TRAIL, and FasL) (Krzewski and Coligan, 2012). Hence, these lytic granules are often called “secretory lysosomes”. Upon NK cell activation, there is polarized degranulation of the lytic granule into the immune synapse. Although NK cell granules contain important lysosomal enzymes required for the activation of cytotoxicity proteins, we will only review the membrane-disrupting and pro-apoptotic proteins contained within them.

One of the best characterized cytolytic molecules stored in NK cell granules is perforin. It is a glycoprotein that has ~20% protein sequence homology with terminal complement proteins. Perforin is constitutively expressed in all developmental stages of NK cells. Cytokine-producing CD56^{bright} NK cells have the lowest perforin expression while cytotoxic CD56^{dim} NK cells have the highest levels of expression. Perforin is produced as an inactive 60–70 kDa globular protein that becomes activated in the presence of calcium ions in the lytic granules (Andrin et al., 1998). Upon release of the granules into the immune synaptic cleft, activated perforin monomers incorporate and polymerize into the plasma membrane of the target cell to form a porous channel (5–20 nm in diameter; 14 nm in length) (Osińska et al., 2014). Although at least 3–4 perforin molecules are sufficient to produce the channel, most channels are comprised of ~20 perforin monomers. Perforin channels are formed not only on the plasma membrane but also

on other membranous structures including the ER/Golgi, endosomes, and the nuclear envelope. The channels allow for the passive transport of water, ions, and macromolecules across all membranes and contribute to osmotic lysis of the cells.

Lytic granules also contain granzysin, a multi-functional protein with cytotoxic, chemoattractant, and pro-inflammatory properties. Like perforin, granzysin is expressed by CTLs and NK cells. Granzysins are 9 kDa proteins that are functionally very similar to defensins in that the positively-charged protein is electrostatically attracted to the negatively charged membrane and permeate through the plasma membrane by a scissoring action (Anderson et al., 2003). Granzysins can also enter via perforin pores. Additionally, granzysin can induce the expression of chemokines (RANTES, CCL8) and cytokines (IL-1, IL-6, type 1 interferons) on the target cell (Krzewski and Coligan, 2012).

Polarized release of the lytic molecules can be organized as a complex in membraneless protein structures called SMAPS, or supramolecular attack particles (Ambrose et al., 2020). Overall, rapid target cell cytotoxicity is induced with perforin and granzysin pathways.

NK cells also produce pro-apoptotic proteins including granzyme B (GzmB), Fas ligand (FasL, CD178), and TNF-related apoptosis-inducing ligand TRAIL (CD253). Similar to perforin, granzyme B is stored in the lytic granules. It is a serine protease that was previously postulated to enter the target cell via perforin pores. More recent models demonstrate that the perforin pores on the target cells induce calcium influx and which activates dynamin-dependent endocytosis of the granzyme that is electrostatically bound to plasma membrane (Chowdhury and Lieberman, 2008; Veugeliers et al., 2004). The protease escapes the endosomal vesicles via perforin pores and enters the cytoplasm. Granzyme B activates multiple cytoplasmic caspases including caspase-3 which triggers DNA and mitochondrial damage pathways. Granzyme B also initiates apoptosis via cleavage of Bid. The net effect is the generation of reactive oxygen species (ROS) which disrupt the mitochondrial membrane potential and release cytochrome C to induce cellular death. GzmB also activates caspase-activated DNase (CAD) which leads to rapid DNA fragmentation and cell death. Separately, FasL and TRAIL are pro-apoptotic molecules that localize to the NK lytic granule and are enriched on the intraluminal membranes of the vesicles (Bossi and Griffiths, 1999; Lee et al., 2018). They initiate apoptosis by engaging death receptors expressed on target cells, Fas (CD95) and TRAIL-R, respectively. This activates pro-apoptotic machinery (namely caspase-8 and -10) which is slow compared to the lytic protein pathways discussed above.

Cytokine dependent function

Unlike perforin and granzyme, NK secreted chemokines/cytokines are packaged into endosomes and are exocytosed in a non-polarized fashion (Reefman et al., 2010). Different subpopulations of NK cells produce proinflammatory and immunosuppressive cytokines that are functionally analogous to T-cell subsets. For example, NK1 cells aid in the induction of a Th₁ response by producing IFN γ and TNF α which is the primary response to intracellular pathogen (Reid-Yu et al., 2013). NK2 cells are analogous to Th₂ cells—they synthesize and secrete IL-4, IL-5, and IL-13 (Peritt et al., 1998; Katsumoto et al., 2004). Finally, regulatory NK cells (NK_{reg}) produce TGF β and IL-10 (Jiang et al., 2018). NK cell cytokine gene transcription is finely regulated by cytokine-induced and activating receptor-mediated activation of transcription factors (STAT-4 and -5, NF κ B, AP-1, and c-Fos/c-Jun). Furthermore, NK cells produce and secrete granulocyte/monocyte colony-stimulating factor (GM-CSF) to activate other leukocytes and chemokines (RANTES, IL-8, MIP-1 α/β) to attract other immune cells (Abel et al., 2018).

Antibody-dependent cellular cytotoxicity (ADCC)

ADCC is a form of cell-mediated immunity whereby IgG-coated target cells are recognized by effector lymphocytes and lead to release of cytotoxic factors that kill the target cells. Importantly, ADCC is not a complement-dependent process. Briefly, the Fab portion of IgG antibodies (IgG1, IgG2, IgG3, and IgG4) recognize antigens on the target cells while the Fc backbone engages the Fc γ Rs on the NK lymphocytes. Natural killer cells have two Fc γ Rs: Fc γ RIIc (CD32c) and Fc γ RIIIa (CD16a), both of which are activating receptors. Fc γ RIIc has a cytoplasmic ITAM that is phosphorylated upon the Fc γ R engaging the antigen-antibody complex. This activates pathways involved in NK cell degranulation, pro-inflammatory cytokine release, and TNF-dependent signaling. In contrast, Fc γ RIIIa associates with Fc ϵ RI- γ or CD3- ζ chains, both of which have ITAMs and activate similar transduction pathways. Polymorphic variants in the Fc γ RIIc and Fc γ RIIIa affect the binding strength to the antibody Fc backbone and subsequent ADCC activity.

NK cells and infectious pathogens

Viral infection

NK cells have important antiviral function and this review will focus primarily on the herpesviridae family.

Herpesviridae: This family of double-stranded DNA viruses includes nine human herpes viruses (HHV) that cause human disease. The viruses are divided into three subfamilies: α -, β -, or γ -herpesviridae. Severe, invasive, and persistent infections by *Herpesviridae* viruses can be seen with various combined immune deficiencies (NEMO deficiency, DOCK8 deficiency, APDS, Wiskott-Aldrich Syndrome, STAT1 GOF, TLR3 deficiency, UNC93b deficiency) and in individuals who have congenital NK cell deficiencies.

α-herpesviridae viruses: this family includes herpes simplex virus-1 (HSV-1, or HHV-1), herpes simplex virus-2 (HSV-2, or HHV-2), and varicella zoster virus (VZV, or HHV-3). The viruses primarily target mucoc epithelial cells and establish latency in neural ganglia. HSV-1 and HSV-2 are major causes of oral/genital herpes infections, gingivostomatitis, eczema herpeticum, herpetic encephalitis, and erythema multiforme. VZV infection causes chickenpox and shingles. Our current understanding of which NK cell receptor-pathways are important for clearance of HSV and VZV come from our knowledge of how the viruses evade these pathways (De Pelsmaeker et al., 2018). HSV-1/2 and VZV have co-evolved with our immune system and developed unique immune evasion mechanisms, different even among the *α-herpesviridae* viruses. In general, virally infected cells express stress-induced ligands which include the polymorphic major histocompatibility complex class I-related chain A and B proteins (MICA and MICB) and UL16 binding proteins (ULPBs). These molecules are activating ligands for NKG2D receptors and natural cytotoxicity receptors (NCRs) on NK cells (Dai and Caligiuri, 2018; Costa et al., 2009). HSV-1 blunts the expression of MICA and ULPBs (Schepis et al., 2009; Campbell et al., 2015). During re-activation, HSV-1 also produces miRH8 to blunt various antiviral pathways. miRH8 decreases expression of the antiviral protein tetherin and decreases expression of GPI-anchored NK cell ligand proteins (ULBP -2 and -3, and the 2B4 ligand CD48) (Enk et al., 2016). In contrast, VZV upregulates MICA expression but reduces ULBP2 and ULBP3 expression (Campbell et al., 2015). VZV can also infect mature NK cell subsets (CD56^{bright}, CD56^{dim}, CD57^{bright}) and alter the expression of NK cell surface receptors (namely CCR4) to enhance NK cell homing to the skin (Campbell et al., 2018). Other immune-evading mechanisms by HSV-1 and -2 include the production of ICP47 (infected cell protein 47, or UL12) which inhibits TAP (transporter associated with antigen presentation), prevent antigen loading on MHC-I, and results in the transport of empty MHC-I molecules (Odom et al., 2012; Cheng et al., 2020). There are known genetic polymorphisms in NKG2D ligands which alter susceptibility to various cancers and rheumatologic conditions (Choy and Phipps, 2010; Zuo et al., 2018), but their role in modulating viral infectivity is less clear.

β-herpesviridae viruses: this family of Herpesviridae viruses includes cytomegalovirus (CMV, or HHV-5) and roseolovirus (HHV-6). Human CMV (HCMV) has the largest genome of the human herpesviruses. It is also the best characterized of the *β-herpesviridae* family with regard to the role of NK cells combating viral infection. CMV is highly prevalent worldwide, particularly in developing countries where >90% of individuals are seropositive (Zuhair et al., 2019). The virus can establish lifelong, latent infections and most individuals with CMV infection are asymptomatic. However, in immunocompromised individuals and neonates, infection can cause hepatitis, gastroenteritis, hearing impairment, retinitis, and pneumonitis. NK cells play an important role in eliminating or containing CMV infection. Like other Herpesviridae viruses, CMV can induce the expression MICA/MICB and ULPBs in infected cell and it has also developed mechanisms to downregulate the expression of these NKG2D ligands. This includes miRNA (miR-UL112)-mediated processes and upregulating UL16 which inhibit MICA/MICB. CMV causes expansion of NKG2C NK cells in both acute infection and with viral reactivation, and alters the NK cell receptor repertoire (Gumá et al., 2004; Barnes et al., 2020). NKG2C recognizes HLA-E, the non-classical class I allele. Furthermore, these NKG2C cells lack expression of other inhibitory receptors (NKG2A) (Jost and Altfeld, 2013). These phenotypic receptor changes are CMV-specific are not present with other viral infections including HSV and EBV (Gumá et al., 2004). There are currently no known NK cell receptors to CMV proteins.

In general, viruses can evade CD8+ T-cell mediated responses by downregulating HLA-I expression or blocking TAP-dependent transport of processed antigen peptides. CMV express US2 and US11 proteins which transfer HLA class I molecules from the endoplasmic reticulum to the cytoplasm where it undergoes degradation. Similarly, the CMV protein US6 blocks TAP-dependent antigen transport. Therefore, clearing CMV infection requires more than cytotoxic T cells.

γ-herpesviridae viruses: this family of Herpesviridae viruses includes Epstein-Bar Virus (EBV, or HHV-4). EBV is transmitted by saliva, infects multiple cell populations (e.g., B cells and NK cells), and establishes latent infection (Howe et al., 2020). While most people with EBV are asymptomatic carriers, EBV can cause infectious mononucleosis (IM) and B-cell and epithelial cell malignancies, namely Burkett's lymphoma and nasopharyngeal carcinoma (Shannon-Lowe and Rickinson, 2019). Additionally, there is preferential expansion of CD56^{dim} NKG2A-expressing cells with acute EBV infections (Png et al., 2021). Additionally, with chronic viral infections, there is an expansion of a subset of NK cells that are CD56-CD16⁺, which most likely represent anergic/exhausted NK cells (Björkström et al., 2010; Lugli et al., 2014). EBV-infected cells expressing CD48 are recognized by the NK cell activating receptor 2B4; non-functional 2B4 contributes to disseminated EBV infection (Tangye et al., 2000). Like other *herpesviridae* viruses EBV evades NK cell recognition by encoding miRNA that downregulate MICA/B and blunting the NKG2D and DNAM-1 activating receptor/co-receptor pathways (Williams et al., 2015). Severe or recurrent EBV infections are seen with most classical NK deficiencies, as discussed later in this chapter.

Other viruses: Recent evidence has demonstrated a robust NK cell response to SARS-CoV2, the causative virus of COVID-19 disease (Maucourant et al., 2020). This includes increased expression of perforin and NKG2C in NK cells (Soleimanian and Yaghoobi, 2020). The antiviral role of NK cells against adenoviruses, respiratory syncytial virus, human papilloma virus, HIV, and influenza virus are reviewed elsewhere (Waggoner et al., 2016; Björkström et al., 2021).

Bacterial infection

Although T-cell and antibody responses are critical for controlling bacterial infections, NK cells are increasingly recognized as important for linking innate immune responses to adaptive immunity (Gabrielli et al., 2016). Activation of NK cells via bacteria-stimulated leukocytes (T/B lymphocytes, PMNs, eosinophils) is reviewed elsewhere (Souza-Fonseca-Guimaraes et al., 2011). NK cells can directly recognize bacterial PAMPs using PRRs and mediate their antibacterial activity predominantly by TNF death receptor signaling, cytotoxic granules, and interferons (Schmidt et al., 2016). For example, *E. coli* fimbrial protein (FimH)

directly activate TLR4/MyD88 signaling in NK cells in an LPS-independent manner and lead to subsequent IFN γ and TNF α secretion (Mian et al., 2010). Clearance of *Klebsiella pneumoniae* lung infection is partly dependent on pathogen proteins (e.g., flagellin, outer membrane protein A) inducing IFN and α -defensin secretion via IRF3, TLR2, TLR4, and TLR5 signaling in NK cells (Ivin et al., 2017; Chalifour et al., 2004). Furthermore, NK cells directly bind to *Mycobacterium* spp. cell wall components (mycolyl-arabinogalactan-peptidoglycan and mycolic acids) and engage in contact-dependent killing of infected cells (Schmidt et al., 2016). For example, vimentin expressed on *M. tuberculosis* (Mtb)-infected monocytes activates Nkp46 to induce non-IFN γ -dependent cell lysis of the infected cells (Garg et al., 2006; Vankayalapati et al., 2002). NK cells also have a role in regulating gut mucosal immunity against *Salmonella* infection (Harrington et al., 2007). Separately, secreted bacterial factors can impair NK cell cytotoxicity pathways or induce NK cell depletion. For example, *B. anthracis* lethal toxin, cholera toxin, and pertussis toxin impair NK cell cytotoxicity and/or motility (Watanabe et al., 1993; Lagadari et al., 2009). Additionally, *Y. pestis* virulence protein YopM inducing global NK cell depletion (Kerschen et al., 2004). Finally, suppression of NK cells by bacteria can increase tumor metastasis. For example, NK cells infected with *Pseudomonas* undergo apoptosis and augment metastasis (Chung et al., 2009). Onco-bacteria such as *Fusobacterium nucleatum* have inhibitor ligands that suppress NK cells and contribute to carcinogenesis (Gur et al., 2015).

Fungal infection

The primary mechanism of antifungal immunity involves a combination of innate (macrophages, polymorphonuclear cells, defensins, cytokines) and adaptive (T and B lymphocytes) immune responses (for a comprehensive review, see Ref. (Romani, 2011)). Recent clinical and scientific evidence have identified novel roles for natural killers cells against fungal pathogens (Schmidt et al., 2017). Clinical studies on patients who have undergone transplants (solid organ; hematopoietic stem cell transplant, HSCT) demonstrated that those with invasive fungal disease (Aspergillosis) often had low number of NK cells (Romani, 2011; Stuehler et al., 2015). It is unclear whether the fungal infection induced the NK cell lymphopenia or if the paucity of NK cells contributed to the development of the infection, but lower absolute NK cells were associated with poor outcome. In vitro studies using human and mouse NK cell lines have demonstrated an important antifungal role for activating NK receptors (NCRs, CD56, and CD16) against *Candida*, *Aspergillus*, and *Cryptococcus* spp. (Li et al., 2013; Ziegler et al., 2017; Nabavi and Murphy, 1986). Furthermore, fungal activation of NK cells induces the secretion of various soluble molecules, namely IFN γ , RANTES, and GM-CSF and can augment classical antifungal pathways in T-cells and PMNs (Bouzani et al., 2011; Marischen et al., 2018). NK cell cytotoxicity against fungi is also mediated per perforin (Ma et al., 2004). Fungal infections are seen in ~10% of patients with classical NK cell deficiency, many of whom have GATA2 deficiency (Spinner et al., 2014; Orange, 2013). Overall, the precise role of NK cells in eliminating fungal pathogens needs to be better characterized both in healthy individuals and immunocompromised patients.

Protozoan infection

Parasites can induce strong host inflammatory responses and activate NK cells. For example, *Plasmodium* spp., the organism responsible for malaria, can directly activate spontaneous and ADCC pathways in NK cells. Patients with uncomplicated malaria infection have high levels of CD56^{bright}, low levels of CD56^{dim} NK cells, and expansion of “adaptive” NK cells (Orago and Facer, 1991; Hart et al., 2019; Tesi et al., 2016). NK cells can directly bind parasite protein during the blood-stage of the parasite life cycle: PfEMP1 with Nkp30 and Nkp46. Interestingly, NK cells lacking CD16 have enhanced protection from malaria. Similar pathways are identified in the cross-talk between NK cells, *Leishmania*, and *Toxoplasma* spp. pathogens (Horowitz et al., 2012).

NK cells in health and human disease

Dysregulation of NK cells has been demonstrated in non-infectious diseases states including malignancy, autoimmunity, and atopic diseases (Mandal and Viswanathan, 2015).

NK cells are the main innate defense cells against cancer cells and have an important role in immunosurveillance (Waldhauer and Steinle, 2008). NK cells are found in tumor cells, albeit in much lower numbers compared to other lymphoid and myeloid cells (Carrega et al., 2014). In fact, upregulation of NKG2D ligands on the surface of many tumor cells recruits NK cells to the tumor (Wang et al., 2019). Furthermore, high numbers of NK cells in the various solid tumors (e.g., GI, lung, breast, brain, and renal cancers) are directly proportional to better survival prognosis (Takeuchi et al., 2001; Best et al., 2020; Nersesian et al., 2020; Sedgwick et al., 2020). Inversely, epidemiologic data has demonstrated that patients with diminished NK cell activity (in the peripheral blood) are at increased risk for developing cancer (Imai et al., 2000). Due to their antitumor potential, NK cells are currently harvested (isolated from umbilical cord, placenta, or peripheral blood) and engineered for cell-based cancer immunotherapy for leukemias and solid-organ cancers (Shimasaki, 2020; Liu et al., 2021a).

NK cells have a significant role in atopic diseases such as atopic dermatitis (AD) and asthma (von Bubnoff et al., 2010; Kim and Jang, 2018). Atopic dermatitis is a complex, type 2 chronic inflammatory skin disease. Patients with severe AD may develop eczema herpeticum and eczema vaccinatum, signs of diminished antiviral immunity. Clinical studies have identified quantitative (diminished CD56^{dim} effector cells) and qualitative dysregulation of NK cells in AD patients in part due to decreased IFN γ production, a potent inhibitor of type 2 inflammation (Mack et al., 2020; Luci et al., 2012; Molofsky et al., 2015). Similarly, NK cells have been

described as “asthma antagonists” and contribute to the resolution of allergic inflammation by suppressing Th₂ cells and IL-17-dependent signaling (Gorska, 2017; Karimi, 2013).

NK cells have been implicated in the development of autoimmune diseases (Type 1 diabetes, systemic lupus erythematosus, rheumatoid arthritis autoimmune encephalitis, multiple sclerosis) and hyperinflammatory disorders. NK cells have protective cytotoxic activity against autoreactive T and B cells, or by cytokine signaling (TGFβ, IL-4, IL-5, and IL-10). However, NK cells can also have a pathogenic role in the development of autoimmune disease by secreting cytokines and chemokines that recruit and activate other immune cells and enhance tissue inflammation and destruction (for a comprehensive review, see Ref. (Liu et al., 2021b)).

NK cell deficiencies

There are numerous immunodeficiencies where abnormalities in NK cells (quantity and/or quality) are present in the setting of other immune defects (Vargas-Hernández and Forbes, 2019). Of the ~430 genes causing primary immune deficiencies (PID) (Tangye et al., 2020), >50 affect NK cells of which only 7 are known to cause true NK cell deficiency (NKD) (Orange and How, 2020). The diagnostic criteria for NKD are as follows:

1. NK cells levels are ≤1% of PBMCs.
2. Depressed NK cell numbers and function on three separate occasions separated by at least 1 month (Bonilla et al., 2015).
3. Exclusion of other PID that affect NK cells (Wood et al., 2011).
4. Exclusion of other causes including malignancy, infection, or medications.

Impaired NK development and/or function is the major immunological defect in these NK cell deficiencies. NKDs which can be categorized based on (1) defects in NK cell receptors, (2) defects in cell transcription factors, or (3) abnormalities in NK cell cycle proteins. Six genes are responsible for classical NKD (cNKD) which include deficiencies in GATA2, MCM4, MCM10, GINS1, IRF8, and RTEL1 (Hsu et al., 2011; Gineau et al., 2012; Cottineau et al., 2017; Mace et al., 2020, 2016; de Vries et al., 1996; Ballew et al., 2013). A hallmark feature of cNKD is the paucity (or complete absence) of NK cell subsets. Additionally, to date there is only one functional NKD (fNKD), due to defects in FCGR3A/CD16 gene (Grier et al., 2012). fNKD present with normal number of NK cell subsets but with abnormal cytotoxicity profile. The following section reviews the biology, clinical and laboratory phenotype, and management of the six known types of NKDs.

GATA2 deficiency (AD)

GATA2 (GATA-binding factor 2; OMIM 614172, Chr. 3) is a zinc-finger containing transcription factor. GATA promotes development and function of hematopoietic stem and progenitor cells (HSPC) and the formation of blood/lymphatic vessels (Ostergaard et al., 2011). GATA2 deficiency was the first identified case of cNKD in a patient that presented with disseminated VZV, CMV, and HSV (Spinner et al., 2014; Mace et al., 2013). GATA2 deficiency has a highly variable penetrance pattern and heterogenous phenotypic expression may be affected by somatic mutations in other genes (RUNX1, ETV6, STAG2, among others) (Bresnick et al., 2020). GATA2 deficient patients are mostly susceptible to viral infections including HPV, HSV, EBC, and molluscum contagiosum. However, they can also develop severe non-tuberculous mycobacterial disease (typically *Mycobacterium avium* complex [MAC], and *M. kansasii*) and fungal infections. GATA2 deficient patients have nearly (or absolutely) absent CD56^{bright} NK cells but can have some CD56^{dim} NK cells with impaired function (Mace and Orange, 2016; Mace et al., 2013). Another prominent feature is multi-lineage cytopenias including B lymphocytopenia, NK lymphopenia, and monocytopenia (Hsu et al., 2011). Lastly, GATA2 deficient patients have increased risk for myeloid malignancy (AML and CMML), pulmonary complications (pulmonary alveolar proteinosis due to pulmonary warts), primary lymphedema, and miscarriage (Griese et al., 2015).

MCM4 deficiency (AR)

MCM4 (Mini-chromosome maintenance complex component 4; OMIM 609981, Chr. 8) is a crucial nuclear subunit of the CMG replicative helicase and is important for maintaining mitotic stability during DNA replication, recombination, and repair. Briefly, the CMG helicase is a 11-subunit complex made up of CDC45 protein, the MCM2-7 complex, and the GINS complex. The MCM2-7 complex is hexameric ring-shaped “motor” that binds to chromatin and gets activated by CDC45 and GINS complex. Defects in the CMG replisome impair cell cycle progression and induces DNA damage (and subsequent activation of DNA damage repair pathways). Partial MCM deficiency was initially reported in six related Irish patients (consanguineous kindred) with variable presentation including intrauterine and postnatal growth restriction, glucocorticoid deficiency, EBV-driven lymphoma, osteosarcoma, and predisposition to viral infections (HSV, VZV) (Gineau et al., 2012; Hughes et al., 2012). Immunophenotyping of the NK cells in these MCMF deficient patients showed reduced total number of NK cells mostly due to the paucity of mature, cytolytic CD56^{dim} NK cells. The selective loss of CD56^{dim} cells resulted in skewing toward higher levels of CD56^{bright} NK cells, similar to other NKDs such as IRF8 and GINS1, as discussed below. The MCM4 deficient CD56^{dim} cells did, however, proliferate with IL-2 and IL-15 stimulation. This suggests that the lack of NK cells was in part due to a large chromosomal genotoxic burden during proliferation of CD56^{bright} cells and inability to generate many CD56^{dim} cells.

MCM10 deficiency (AR)

MCM10 (Mini-chromosome maintenance complex component 10; OMIM 619313, Chr. 10) is a key scaffold protein within the CMG replisome (Di Perna et al., 2013). It is active during cellular proliferation and is crucial for the formation of replication forks, maintenance of telomere integrity, and prevents genomic instability (Miotto et al., 2014; Chattopadhyay and Bielinsky, 2007). MCM10 is upregulated in various tumors including medulloblastoma and breast cancer (Senfter et al., 2017; Murayama et al., 2021). MCM10 deficiency (due to biallelic mutations in the MCM10 gene) was first identified in an infant presenting with febrile illness, organomegaly, diarrhea, and disseminated CMV disease (Mace et al., 2020). He had severely low total NK cells, with an overrepresented CD56^{bright} population, similar to MCM4 deficiency. HSCT was unsuccessful in this patient due to fatal CMV infection. Separately, frameshift variants in the MCM10 genes in three other unrelated patients produced a different phenotype with restrictive cardiomyopathy and splenic/thymic hypoplasia (Baxley et al., 2021). Overall, clinical and basic science data provides convincing evidence for the role of MCM10 in NK cell development/function and its role in other somatic cells.

GINS1 deficiency (AR)

GINS (Go-Ichi-Nii-Sans, or 5, 1, 2, and 3 in Japanese; OMIM 617827, Chr. 20) is an evolutionarily conserved chromosomal DNA replication complex initially identified in budding yeast (Takayama, 2003). GINS subunit 1 (GIN1) is a component of the hetero-tetrameric GINS complex (GIN1, -2, -3, and 4). During the G1/S transition phase of mitosis, the GINS complex interacts with CDC45 and MCM2-7 to form a macromolecular replisome. GINS preferentially binds to ssDNA and may have a direct role in unwinding the DNA during replication (Boskovic et al., 2007). In murine models, deletion of *Gins1* is embryonically lethal. In humans, compound heterozygous mutations of GINS1 were initially identified in two French sisters who presented with intrauterine growth restriction, postnatal growth restriction, facial dysmorphism, lymphadenopathy, and eczema. They had immunological defects including neutropenia, CD8 $\alpha\beta$ T cells lymphopenia, and absent or extremely low number of NK-cells (both CD56^{bright} and CD56^{dim} NK cells) (Bernard et al., 2004). Additional individuals with GINS1 deficiency from other unrelated and non-consanguineous families have been identified and have similar immune phenotypes (Cottineau et al., 2017). GINS1 deficient patients mostly have severe viral infections caused by VZV, CMV, HSV, RSV, and adenovirus. At the cellular level, GINS1 deficient patients have approximately 25–50% of the GINS1 protein expression compared to healthy individuals and their cells have lower number of replication forks, abnormal cell cycle control (slower proliferation), genomic instability, and signs of cellular senescence (Cottineau et al., 2017). While the neutropenia in GINS1 patients can be reversed with G-CSF, there are currently no treatments available for the NK cell deficiency. Additionally, given the important role of GINS in maintaining chromosomal stability, the potential risk for malignancy associated with GINS1 deficiency is unknown.

IRF8 deficiency (AR)

IRF8 (interferon regulatory factor 8; OMIM 601565, Chr. 16) is a transcription factor that is exclusively found in cells with hematopoietic lineage and is highly expressed in plasmacytoid dendritic cells (Sichien et al., 2016). IRF8 binds to the interferon consensus sequence (ICS) upstream of type I IFN and IFN-inducible MHC class I genes which are upregulated during viral infection. IRF8 also has other pleiotropic effects including regulation of apoptotic pathways (Yang et al., 2011). Homozygous and heterozygous IRF8 mutations in mice and humans lead to abnormal differentiation of mononuclear phagocytes and play a critical role in anti-mycobacterial immunity (Hambleton et al., 2011). Additionally, biallelic mutations in IRF8 can cause life-threatening EBV infection (Mace et al., 2016; Fleisher et al., 1982). At the cellular level, viral-infected cells secrete IL-12 or common- γ -chain dependent cytokines (IL-12, IL-15) which upregulate IRF8 expression in NK cells (Adams et al., 2018). IRF8 directly controls Zbtb32, a master regulator of the NK cell proliferative burst, and regulates expression of other cell cycle genes that are critical for cellular maturation and survival (Adams et al., 2018; Beaulieu et al., 2014). In mice, *Irf8* ablation adversely blunts NK-cell proliferation during acute CMV infection (Adams et al., 2018). In humans, IRF8 deficient patients have impaired NK cell function and a paucity of cytotoxic CD56^{dim} NK cells, reflecting impaired NK cell terminal maturation (Mace et al., 2016). There are currently no good treatment strategies available for IRF8 deficiency but cord-blood stem cell transplantation has been previously successful in an infant with IRF8 deficiency and disseminated BCG disease (Hambleton et al., 2011).

RTEL1 deficiency (AR/AD)

RTEL1 (regulatory of telomerase elongation 1; OMIM 608833, Chr. 20) is a DNA helicase with antirecombinase activity. RTEL1 is important for maintaining telomere length and limiting excessive meiotic crossovers. In general, mutations in helicases can cause developmental delay, dyskeratosis congenita (DC), pulmonary fibrosis, hepatic disease, bone-marrow failure, and myelodysplastic syndrome. Mutations in the RTEL1 helicase can cause a very severe variant of DC called Hoyerall Hreidarsson (HH) syndrome. HH patients present with immunodeficiency, enteropathy, IUGR, and CNS hypoplasia. RTEL1 deficient patients are at risk for viral infections (e.g., VZV) and immune phenotyping reveals either isolated NK cell lymphopenia and impaired cytotoxicity (Etzioni et al., 2005), or B/NK cell combination quantitative and qualitative defects (Speckmann et al., 2017). Importantly, although this helicase is important for DNA repair, V(D)J recombination and T-circle accumulation is not affected in RTEL1 deficient patients (Speckmann et al., 2017). This is consistent with the fact that NK cells do not undergo V(D)J recombination to generate their large repertoire of antigen receptors, which are germline encoded (Karo and Sun, 2015). HSCT has been successful in two cases of RTEL1 deficiency (Speckmann et al., 2017).

FCGR3A (CD16) deficiency (AR)

FCGR3A (Fc fragment of IgG receptor 3a, or CD16; OMIM [146740](#), Chr. 1) encodes for a low affinity, IgG-binding (IgG1 or IgG3), transmembrane glycoprotein receptor. CD16 is expressed on NK cells, activated monocytes/macrophages, and natural killer T cells. Activation of CD16 stimulates Ca^{2+} -dependent pathways that increase expression of various cytokines and exocytosis of secretory lysosomes in both spontaneous and antibody-dependent cytotoxicity assays, as discussed above. Patients with homozygous mutations in FCGR3A can present with otitis media, sinusitis, URIs, and susceptibility to various viral infections (HSV, HPV, CMV, EBV; stomatitis, whitlow, Castleman's disease) (de Vries et al., 1996; Jawahar et al., 1996). Most of the known human mutations in FCGR3A (e.g., L66H) are located distal to the IgG-binding domain of the receptor (recognized by B73.1 anti-CD16 antibody) (Orange, 2013). In healthy patients, this region of CD16 engages with as co-stimulating receptor for CD2 and is important for spontaneous cytotoxic function. The variant does not affect receptor expression or binding of IgG to CD16. Hence, L48H mutations in FCGR3A are associated with abnormal spontaneous cytotoxicity and normal ADCC. To date, there are no known mutations in the IgG-binding domain of CD16 (recognized by 3G8 anti-CD16 antibody). Overall, patients with FCGR3A deficiency have quantitatively normal number of NK cell subtypes but have abnormal cytotoxicity profiles. Hence, unlike the other NK deficiencies discussed above, FCGR3A is a functional NK cell deficiency.

Summary

NK cells are innate lymphocytes involved in defenses against pathogen-infected, senescent, and malignant cells. Advances in medical and basic sciences in the last 50 years have allowed us to better characterize the complex biology of NK cells. We are now in an exciting, yet challenging, position to translate the wealth of knowledge into therapeutic application in various disease conditions.

Pattern recognition receptors: As the sensors for pathogen-associated molecular patterns

The innate immune system is defined as the first line of host defense against invasive pathogens by discrimination of “non-self” from “self” antigens. Recognition by innate immune cells depends on germline-encoded pattern-recognition receptors (PRRs) which have specialized to recognize the conserved structures of foreign pathogens called pathogen-associated molecular patterns (PAMPs). In this regard, the engagement of PRRs with their ligands triggers the pro-inflammatory responses resulting in pathogen elimination (Takeuchi and Akira, 2010).

PRRs are also responsible for detecting the endogenous molecules released by dying or damaged cells referred to as Damage-Associated Molecular Patterns (DAMPs). Recognition of DAMPs as danger signals initiate or propagate sterile inflammation leading to tissue repair and regeneration (Takeuchi and Akira, 2010).

In addition to their roles in host defense, PRRs signaling plays an important role in immune system homeostasis. In this context, inappropriate receptor activation could result in developing a variety of diseases such as neurodegenerative disorders (Hanke and Kielian, 2011), autoimmune diseases (Farrugia and Baron, 2017), cardiovascular disorders (Moghimpour Bijani et al., 2012), and cancer (Khajeh Alizadeh Attar et al., 2018).

Four primary families of PRRs including Toll-like receptors (TLRs), nucleotide-binding oligomerization domain (NOD)-Leucine Rich Repeats-containing receptors (NLR), retinoic acid-inducible gene 1 (RIG-1) -like receptors (RLR), and the C-type lectin receptors (CLRs) have been identified which are differently diffused in subcellular compartments such as cytosol, cell membrane, and endosomal membrane (Takeuchi and Akira, 2010).

TLRs are the well-known PRRs which play an important role in priming the inflammatory responses and mounting efficient immune responses. This chapter attempts to survey the biology and significance of TLRs activation in host defense.

Toll-like receptors (TLRs)

TLRs were the first discovered PRRs which acknowledged as important receptors involved in homeostasis of the immune system and establishing host immunity to infections. TLRs are mostly expressed on antigen-presenting cells (APCs), in particular macrophages and dendritic cells promoting the phagocytic activity such as pathogen uptake and killing by APCs (Medzhitov, 2001). The TLR functions depend closely on where they are expressed; in the epithelial cells they promote the production of anti-microbial peptides as the first line of defense at mucosal sites. For example, activation of TLR4 in the Paneth cells of the intestine results in high production of defensins; however, in the absence of infection, they are involved in the enhancement of tight junctions and tissue homeostasis (Menendez et al., 2013; Hug et al., 2018).

TLRs also act as a bridge between innate and acquired immune responses. Ligand-induced activation of these receptors leads to recruitment of leukocytes to the infected tissues. This process is enhanced by the expression of adhesion molecules such as E-selectin and ICAM1 on endothelial cells induced by TLRs. Besides, TLR engagement on APCs induces the expression of co-stimulatory molecules such as B7.1 (CD80) and B7.2 (CD86), which are essential for CD4⁺ T cells activation and triggering adaptive immunity (Iwasaki and Medzhitov, 2004).

TLRs tend to be involved in tissue homeostasis, in addition to their functions in host immunity against infection. In this manner, the production of prostaglandins, cyclooxygenase 2 (COX2), and the expression of anti-apoptotic proteins induced by TLR signaling plays a crucial role in tissue repair and regeneration (Fukata et al., 2006; Brown et al., 2007). This function is of utmost importance; so that the improper or inappropriate activation of such receptors might contribute to the development of various disorders such as cancer, autoimmunity, brain, and cardiovascular diseases, whether in the context of infection or not.

Structure of TLRs

TLRs are classified as type I integral membrane proteins that consist of three domains as follows (Fig. 1) (Jin and Lee, 2008):

- 1- Extra-cellular or N-terminal domain is a glycosylated protein composed of tandem repeats of a motif called leucine-rich repeat (LRR) responsible for ligand recognition.
- 2- Intra-cellular or C-terminal region of TLRs includes a domain known as Toll IL-1 receptor (TIR) contributing to signaling cascade upon TLR activation.
- 3- The transmembrane region is a single-pass helix containing typical hydrophobic amino-acids. This part is involved in TLR dimerization and stabilization.

Of note, all TLRs form a hetero- or homo-dimer structure upon ligand binding that facilitates their signal transmission process.

Cellular expression of TLRs

TLRs are widely expressed in both immune- and non-immune cells enabling antimicrobial responses to be triggered in several tissues. Dendritic cells (DC), macrophages, and B cells are the prominent immune cells expressing TLRs. Fibroblast cells, epithelial cells, osteoblasts, endothelial cells, and hematopoietic stem cells (HSC) are the other TLRs-expressing cells. Up to now, 10 TLRs in humans (TLR1–10) and 12 TLRs in mouse (TLR1–9, TLR11, TLR13) have been identified. They are mostly classified based on their cellular localization; TLR1, 2, 4, 5, 6, 11 are located on the cell surface, while others like TLR3, 7, 8, 9, 10, 12, 13 are found in the intracellular compartments such as the membranes of endosomes, endoplasmic reticulum (ER), and lysosomes (Table 1) (El-Zayat et al., 2019).

TLRs recognize both intra- and extra-cellular molecular patterns

Any particular TLR is devoted to identifying a distinct molecular pattern. For clarify, Table 1 displays TLRs along with their associated ligands. In contrast to the cell surface TLRs which are contributing to the recognition of the external antigenic structures of pathogens such as proteins, lipids, and lipoproteins, intracellular TLRs are responsible for responding to pathogens- or host-derived nucleic acids.

Cell surface TLRs: The sensors for external antigenic patterns

TLR2 by forming heterodimers with TLR1 or TLR6 identifies various molecular patterns of Gram-negative bacteria including lipoteichoic acid and lipoproteins. TLR2/1 heterodimers mostly recognize triacyl lipoproteins, while TLR2/6 heterodimers tend to interact with diacyl lipoproteins (Hedayat et al., 2012). They are expressed on DCs, macrophages, basophils, eosinophils, mast cells, endothelial, and fibroblast cells. Recent studies also illustrate the formation of TLR2/TLR10 heterodimers; however, their function and ligands have not been clearly described (Guan et al., 2010).

Fig. 1 TLR structure and signaling pathway. TLRs consist of three domains: 1) Extra-cellular or N-terminal domain responsible for ligand recognition; 2) Intra-cellular or C-terminal region contributing to signaling cascade upon TLR activation; 3) The transmembrane region involving in TLR dimerization and stabilization. All TLRs form a hetero- or homo-dimer structure upon ligand binding. TLR signaling induces a wide spectrum of intracellular responses resulting in the production of pro-inflammatory or anti-viral cytokines. Most TLRs use MyD88 for initiating downstream signaling pathway, except for TLR3 which interacts only with TRIF. TLR4 employs both of MyD88-dependent or TRIF signaling pathways. MyD88 consists of two main domains including TIR domain at C-terminal which interacts with TIR domain at cytoplasmic tails of TLRs, and death domain at N-terminal which recruits IRAKs including IRAK4 and IRAK1.

Recently, a number of accessory molecules and co-receptors have been identified for accumulation of microbial products on the cell surface or within phagosomes to facilitate TLR2 responses. For example, CD36 binds to diacylglycerol and acts as a transporter to deliver it to accessory molecule CD14 which in turn, facilitates ligand loading onto TLR2/TLR6 or TLR2/1 heterodimers (Hedayat et al., 2012). Although CD14 and CD36 are not the essential prerequisites for TLR2 signaling, it is notable that the function of these molecules is to improve responses and decrease the ligand concentrations required for recognition and receptor signaling.

TLR4 is expressed on the numerous cell types including antigen-presenting cells, endothelial cells, myocytes, thyroid cells, endometrial cells, mesangial cells, and adipocytes. TLR4 has been identified as the most important receptor for inflammatory response against lipopolysaccharide (LPS) derived from gram-negative bacteria. For its recognition, TLR4 requires accessory molecules including myeloid differentiation 2 (MD-2) and CD14, which are essential for enhancing the downstream signaling cascade. In the serum, LPS is directed to CD14 by forming a complex with LPS binding protein (LBP). Association of CD14 with TLR4 forms an effective receptor for LPS recognition. TLR4 is also responsible for responding to other components of gram-positive and gram-negative bacteria such as teichuronic acid and mannuronic acid polymers, respectively (Vaure and Liu, 2014).

In addition to PAMPs, some endogenous molecular patterns were also identified as the ligands for TLR4 and TLR2 which could trigger inflammatory responses during tissue damage or necrosis; including heat shock proteins (HSPs), uric acid crystals, fibronectin type III, high mobility group box 1 (HMGB1), surfactant protein A, saturated fatty acids, and heparan sulfate (Roh and Sohn, 2018).

Table 1 Cellular distribution, and known ligands of human Toll-like receptors.

TLR type	Cellular distribution ^a	Expressing cell type	Exogenous ligands ^b	Endogenous ligands ^b	Transcription factor Activation		Cytokine production
					NF- κ B	IRF	
TLR1	Cell membrane	Monocyte/macrophage, Neutrophils, B cell, PDCs MDSCs	Bacteria: • Triacyl Lipopeptides (e.g. <i>N. meningitidis</i>)	N/A	+	–	Pro-inflammatory cytokines
TLR2	Cell membrane	Monocyte/macrophage, Neutrophils, MDCs, Mast cells	Bacteria: • Peptidoglycan, Lipoprotein/lipopeptides, Lipoteichoic acid (Gram positive bacteria) • Modulin (<i>Staphylococcus</i>) • Lipoprotein/lipopeptides (<i>Mycoplasma</i> , <i>Mycobacteria</i> , <i>Spirochetes</i>) • Glycolipids (<i>Spirochetes</i>) • Heat-killed bacteria (<i>Listeria</i>) • lipoarabinomannan (<i>mycobacteria</i>) • Porins (<i>Neisseria</i>), Soluble factors (<i>N. meningitidis</i>) • OmpA (<i>K. pneumoniae</i>) • Outer membrane protein A (<i>Klebsiella</i>) • Soluble factors (<i>Neisseria meningitidis</i>) Virus: • Hemagglutinin (<i>measles virus</i>), structural viral proteins (<i>herpes simplex virus</i> , <i>cytomegalovirus</i>) • Fungi: Zymosan (<i>Saccharomyces</i>) phospholipomannan (<i>C. albicans</i>) Protozoa: • Glycoinositolphospholipids (<i>Trypanosoma cruzi</i>) Yeast: • Zymosan	HSP60, HSP70; hyaluronic acid, HMGB1, versican, GP96	+	–	Pro-inflammatory cytokines
TLR3	Endosomal membrane	MDCs, T cell, B cell	Virus: • dsRNA	mRNA	+	+	Proinflammatory cytokines, type I IFNs
TLR4	Cell membrane	Monocyte/macrophage, Neutrophils, MDCs, Mast cells, B cell, intestinal epithelium	Bacteria: • Lipoteichoic acid (Gram positive bacteria) • LPS (Gram negative bacteria) Virus: • Fusion proteins (<i>respiratory syncytial virus</i> and mouse mammary tumor virus) Fungi • Mannan Protozoa: • Glycoinositolphospholipids (<i>Trypanosoma cruzi</i>)	Hsp60, HSP22, HSP70, HSP72, Gp96, HMGB1, Oxidized phospholipids, Heparin sulfate, Fibronectin, Tenascin-C, b-Defensin 2, Versican, Hyaluronic acid	+	+	Proinflammatory cytokines, type I IFNs
TLR5	Cell membrane	Monocyte/macrophage, Neutrophils, MDCs, intestinal epithelium	Bacteria: • Flagellin (flagellated bacteria)	N/A	+	–	Proinflammatory cytokines

(Continued)

Table 1 (Continued)

TLR type	Cellular distribution	Expressing cell type	Exogenous ligands	Endogenous ligands	Transcription factor Activation		Cytokine production
					NF- κ B	IRF	
TLR6	Cell membrane	Monocyte/macrophage, Neutrophils, Mast cells, MDCs, PDCs, B cell	Bacteria: • Diacyl lipopeptides (e.g. <i>mycoplasma</i>), Lipoteichoic acid Fungi: Zymosan (<i>Saccharomyces</i>)	N/A	+	–	Proinflammatory cytokines
TLR7	Endosomal membrane	Monocyte/macrophage, Neutrophils, DCs, B cell	Virus: • ssRNA	ssRNA (immune complex)	+	+(IRF5, IRF7)	Proinflammatory cytokines, type I IFNs
TLR8	Endosomal membrane	Monocyte/macrophage, Neutrophils, MDCs, Mast cells	Virus: • ssRNA	ssRNA (immune complex)	+	+(IRF5, IRF7)	Proinflammatory cytokines, type I IFNs
TLR9	Endosomal membrane	Monocyte/macrophage, Neutrophils, PDCs, B cell, T cell	Bacteria and virus: • Unmethylated CpG DNA Protozoa: • Unmethylated CpG DNA • Hemozoin (<i>Plasmodium</i>)	N/A	+	+(IRF5, IRF7)	Proinflammatory cytokines, type I IFNs
TLR10	Cell membrane	Monocyte/macrophage, B cell	Bacteria: • Triacylated lipopeptides	N/A	+	–	Proinflammatory cytokines

NF- κ B: Nuclear factor- κ B; IRF: Interferon regulatory factor; MDSCs: Myeloid dendritic cells; PDCs: Plasmacytoid dendritic cells; HSP: Heat shock protein; GP96: Glycoprotein96; HMGB: high mobility group box; OmpA: outer membrane protein A; ssRNA: Single-strand RNA; dsRNA: double-strand RNA; IFN: interferon; CpG: cytosine-guanine dinucleotide; NA: not available.

TLR5 is expressed on macrophages, DCs (especially intestinal lamina propria DCs), and basolateral pole of intestinal epithelial cells. This receptor acts as an immune sensor for capture flagellin, a protein that is found on motile bacteria (Uematsu et al., 2006). TLR11 was also initially determined to detection of flagellin, but is not expressed in humans. TLR11-deficient mice have shown to be susceptible to pathogens carrying flagellin (Hatai et al., 2016).

Intracellular TLRs: The sensors for nucleic acids

Intracellular TLRs are involved in immune response to pathogens- or host-derived nucleic acids. They are mostly located on endosomal compartments, and the acidification of endosomes is required for their activation. UNC93B1, an ER protein, facilitates intracellular trafficking of TLRs from the ER to the endolysosomes (Blasius and Beutler, 2010).

TLR3 is expressed by macrophages, myeloid DCs (importantly CD141⁺ DCs), epithelial cells, fibroblasts, neuronal cells, astrocytes, and skeletal muscle cells. This receptor intrinsically plays a fundamental role in detecting virus-derived double-strand RNA (dsRNA) and activating inflammatory responses by inducing the production of pro-inflammatory cytokines. In particular, the expression of TLR3 is up-regulated by type I interferons (IFN α , IFN β) which promote the antiviral responses. Intriguingly, although several studies suggest that TLR3 improves the eradication of particular viruses, some reports indicate that certain viruses may benefit from TLR3 activation (Vercammen et al., 2008). For example, up-regulation of TLR3 induced by Influenza A virus in the respiratory tract causes acute pneumonia; While, TLR3 was suggested to have a protective role during encephalopathy caused by the influenza A virus (Hidaka et al., 2006).

TLR7 and TLR8 are endosomal sensors for the detection of single-strand RNA (ssRNA) derived from multiple viruses such as HIV-1 or the influenza virus. TLR9 identifies unmethylated CpG (cytosine-guanine dinucleotide) motifs that are present in the genome of viruses and bacteria especially in HSV-1 (Herpes simplex virus 1), MCMV (Murine cytomegalovirus), adenovirus, and poxviruses (Carty and Bowie, 2010).

TLR7 and TLR9 are primarily expressed by plasmacytoid dendritic cells (pDC), B cells, and eosinophils, while TLR8 has shown to be expressed on monocytes and macrophages. All these receptors induce the expression of interferon type I and pro-inflammatory cytokines upon RNA virus detection (Cervantes et al., 2012).

TLR10 expression can be induced in dendritic cells, eosinophils, B cells, neutrophils, and trophoblast cells. It is proposed that TLR10 can form heterodimers with TLR2. In contrast to the other TLRs, little is known about the ligands and biological function of TLR10. Interestingly, its inhibitory functions were shown in one study using transgenic mice. In this context, TLR10 suppresses inflammation by inducing the anti-inflammatory cytokine IL-1Ra through PI3K/Akt signaling pathway (Oosting et al., 2014).

TLR signaling pathway

TLR signaling induces a wide spectrum of intracellular responses resulting in the production of pro-inflammatory or anti-viral cytokines. Upon ligand binding, TLRs actively form dimers which cause their TIR domains to be placed next to each other. Further, the interaction between TIR domains and cytoplasmic adaptor molecules initiates intracellular signaling (Fig. 1) (Kawasaki and Kawai, 2014).

Four adaptor molecules have been identified to interact with distinct TLRs:

- 1- Myeloid differentiation primary response 88 (MyD88)
- 2- Toll-interleukin 1 receptor (TIR) domain-containing adaptor protein (TIRAP) which also known as MAL
- 3- TIR-domain-containing adapter-inducing interferon- β (TRIF)
- 4- TRIF-related adaptor molecule (TRAM)

Most TLRs employ MyD88 for initiating downstream signaling cascade, except for TLR3 which interacts only with TRIF. TLR4 uses both of MyD88-dependent (MyD88/TIRAP) or MyD88-independent (TRIF/TRAM) signaling pathways.

MyD88-dependent pathway

The MyD88 adaptor protein is used by both cell surface TLRs (TLR1/2, TLR2/6, TLR4, TLR5) and endosomal TLRs (TLR7, TLR8, TLR9) to activate signaling pathway (Kawasaki and Kawai, 2014).

MyD88 consists of two main domains including: 1) TIR domain at C-terminal of MyD88 protein which interacts with TIR domain at cytoplasmic tails of TLRs; 2) Death domain at N-terminal of MyD88 which recruits IL-1R-associated kinases (IRAKs) including IRAK4 and IRAK1 (Fig. 1). These kinases being activated via self- and cross-phosphorylation and form an appropriate signaling scaffold that mediates phosphorylation of the other recruited molecules. TRAF6 (tumor necrosis factor receptor-associated factor 6) is one of the important downstream molecules recruited and activated through phosphorylation by IRAKs (Deguine and Barton, 2014).

TRAF6 as an E3 ubiquitin ligase by forming a poly-ubiquitin chains makes a complex with other molecules including transforming growth factor β -activated kinase (TAK1), TAK1-binding protein 1 (TBP1), and TAK1-binding protein 2 (TBP2). Consequently, the activation of TAK1 leads to the initiation of NF κ B signaling pathway.

In the inactivated state, NF κ B is regulated and inhibited by I κ B protein in the cytoplasm. Activating NF κ B as a transcription factor requires phosphorylation and degradation of I κ B that is mediated by a kinase known as IKK β .

Besides, activation of TAK1 may stimulate MAP kinase and JNK signaling pathways resulting in activation of another transcription factor known as activator protein-1 (AP-1) (Chen, 2012; Ajibade et al., 2013).

Notably, with regards to the endosomal TLRs which use MyD88 as an adaptor molecule, IRAK1/4 recruitment may also trigger another signaling pathway. In this way, IRAK1/4 recruits TRAF3 which in turn engages other signaling molecules including IKK and TBK1. These two kinases phosphorylate and activate IFN regulatory factor 7 (IRF7) which translocates to the nucleus where it can derive transcription of interferon type I gene as the anti-viral response (Kawasaki and Kawai, 2014).

Both NF κ B and AP-1 induce multiple inflammatory immune responses leading to the promotion of T cells activation; including the expression of many pro-inflammatory cytokines such as IL-1, IL-6, TNF- α , expression of co-stimulatory molecules B7.1 (CD80), B7.2 (CD86), and up-regulation of CD40 and MHC II (Khajeh Alizadeh Attar et al., 2018).

The activation of NF κ B and AP-1 transcription factors by TLRs is critical to enhancing the immune responses against bacterial pathogens. For instance, mutations in IRAK4 or MyD88 lead to a type of immunodeficiency characterized by recurrent bacterial infections. We will describe the important immunodeficiencies affected by the impaired TLR signaling in the next part.

MyD88-independent pathway

As described earlier, some TLRs such as TLR3 and TLR4 use MyD88-independent signaling pathway upon ligand binding. In contrast to TLR4 which uses either MyD88 or TRIF, TLR3 initiates its signaling cascade only by mediating TRIF adaptor molecule. Signaling using TRIF leads to activation of NF κ B and AP-1 transcription factors, same as MyD88 (Kawasaki and Kawai, 2014).

One of the important downstream mediators of TRIF signaling, known as TRAF3, by making poly-ubiquitin scaffold (like TRAF6) recruits IKK and TBK1 kinases which phosphorylate and activate IRF3. Finally, IRF3 translocates to the nucleus and mediates transcription of interferon type I cytokine (Ajibade et al., 2013). Therefore, activation of both pathways, whether by MyD88 or not, contributes to the enhancement of inflammatory and antiviral responses resulting in the enhancement of pathogen clearance.

Primary immunodeficiencies associated with TLR signaling: Increased susceptibility to infectious diseases

A few numbers of rare immunodeficiencies have been reported associated with impaired TLR signaling and NF κ B activation. Besides, different single-nucleotide polymorphisms (SNPs) were identified in TLRs associated with the increased susceptibility to infectious diseases (Mukherjee et al., 2019) (Table 2).

The important genetic disorders related to TLR signaling are as follows:

Table 2 Association between TLR and susceptibility to infectious diseases.

TLR	Association with diseases					TLR's SNPs associated with infectious diseases ^b
	Cancer ^a			Autoimmunity	Other disorders	
	Cancer type	Role in tumor progression	Role in tumor regression			
TLR2	Gastric, hepatocellular carcinoma	• Immunosuppression • Angiogenesis and Metastasis of tumor • Increase inflammation and Vascularization • Upregulation of Cox-2 and IL8 up-regulation	• Increase of chemosensitivity	• RA: Increased TLR2 on both peripheral blood monocytes and synovial tissues • MS: Increased TLR2 on CNS endothelial cells, microglia, astrocytes and oligodendrocytes, peripheral blood, and in demyelinating lesions of the patients • SSC: Interaction of SSA with TLR2 results in high production of IL-6 which plays an important role in fibrotic effects in dermal fibroblasts. • Psoriasis: Increased expression of TLR2 in keratinocytes • Sjogren's syndrome: Increased expression of TLR2/1 and TLR2/6 heterodimers in salivary gland epithelial cells and PBMCs	• Brain disease: - Astrocytes: express TLR2 which contribute to inflammatory responses - Oligodendrocytes: express TLR2 associated with CNS repair process, immune response regulation, and gliosis. - Bacterial infections and meningitis: anti-bacterial immunity - Parasite infections: protective role or disease severity - Neuronal damage • Diabetes: TLR2 expression associated with higher inflammatory responses, progression of atherosclerosis • Cardiovascular disease: Induction of apoptosis	• Susceptibility to leprosy and tuberculosis • Increased severity of genital herpes • Susceptibility to staphylococcal disease and tuberculosis • Protection from Lyme disease
TLR3	Breast, colon, cervical, head and neck, lung, and prostate cancers; hepatocellular carcinoma, melanoma, myeloma	• Tumor cell proliferation • Tumor cell survival	• Apoptosis • Production of type-1 interferon	• RA: Increased TLR3 on synovial tissues • MS: TLR3 engagement on the normal astrocytes stimulate the production of anti-inflammatory cytokines such as IL-10, which have an important role in down-	• Brain disease: - Astrocytes express TLR3 which contribute to inflammatory responses - Oligodendrocytes express TLR3 associated with CNS repair process, immune response regulation, and gliosis.	• Susceptibility to HSV encephalitis

Table 2 (Continued)

TLR	Association with diseases					TLR's SNPs associated with infectious diseases
	Cancer			Autoimmunity	Other disorders	
	Cancer type	Role in tumor progression	Role in tumor regression			
				regulating inflammation and homeostasis regulation in the brain • SSc: Increased expression of TLR2 associated with disease progression • Psoriasis: Increased expression of TLR2 in keratinocytes, interaction of dsRNA-LL37 complex with TLR3 • Sjogren's syndrome: Increased expression of TLR3 in salivary glands associated with apoptosis and the production of inflammatory cytokines	- Neurons: express TLR3 associated with both physiological and pathological conditions. - Viral infections: TLR3 expression associated with anti-viral immunity and neuronal repair	
TLR4	Breast, colon, gastric, and lung cancers; hepatocellular carcinoma, melanoma	• Tumor cell Proliferation • Immunosuppression • Up-regulation of VEGF, NO, MMPs • Tumor cell growth • Reduced apoptosis • Treg stimulation	• Increase of chemosensitivity • Apoptosis induction • Treg inhibition • Increased antigen presentation	• RA: Increased TLR2 on both peripheral blood monocytes and synovial tissues • MS: TLR4 is increased in the CSF mononuclear cells of MS patients • SSc: Involvement of TLR4 with its ligands leading to enhance fibrotic process and tissue damage. • Sjogren's syndrome: Increased expression of TLR4 in salivary glands associated with glandular inflammation	• Brain disease: - Alzheimer's disease: expression of TLR4 associated with response to amyloid beta - Bacterial infections and meningitis: anti-bacterial immunity - TLR4 may associate with neuronal damage • Diabetes: TLR4 expression associated with higher inflammatory responses, progression of atherosclerosis • Cardiovascular disease: decrease of apoptosis, Increased expression of TLR4 in atherosclerotic lesion	• Susceptibility to infection with gram-negative bacteria, <i>malaria</i>, and <i>RSV</i> • Susceptibility to meningococcal sepsis • Protection from Legionnaires' disease

Anhydrotic ectodermal dysplasia with immunodeficiency (EDA-ID)

EDA-ID is an X-linked recessive immunodeficiency characterized by abnormalities in ectodermal development, including absent or decreased dental and hair growth. This disorder caused by mutation in NEMO, a central member of the IKK complex leading to improper NF κ B activation. The patients are susceptible to infection with encapsulated pyogenic bacteria, such as *S. aureus*, *S. pyogenes*, and *Haemophilus influenza*, as well as mycobacteria, herpesviruses, fungal infections, importantly *P. jirovecii* pneumonitis. NK abnormalities, hyper immunoglobulin M syndrome, decreased response to LPS, TNF, and IL-1 are the important features of EDA-ID patients (Keller et al., 2011).

IRAK4 deficiency

This is an autosomal recessive genetic disorder. The affected patients revealed a decreased inflammatory responses and persistent pyogenic bacterial infections, considerably with *S. pneumonia*. Given the central role of IRAK4 in TLR signaling, its mutation results in the impaired NF κ B and MAPKs activation. Interestingly, the isolated blood cells from these patients fail to produce the inflammatory cytokines in response to different TLR agonists. A similar phenotype was reported in MyD88 deficiency characterized by recurrent pyogenic infections particularly early in life. Thus, it is concluded that both IRAK4 and MyD88 are essential in protective immunity against bacterial infections (Picard et al., 2010).

TLR3 deficiency

TLR3 deficiency is a rare genetic disorder in which the patients are more susceptible to HSV encephalitis. Therefore, TLR3 plays an important role in immunity against central nervous system infections. In this regard, the lack of UNC-93B is also reported to be associated with HSV encephalitis (Lim et al., 2014).

TLR: Roles in human diseases

In recent years, TLRs have attracted attention not only for responding to pathogen components, but also for their function in several disorders including cancer, autoimmunity, brain disease, and cardiovascular diseases (Table 2).

Cancer

Anti-tumoral roles of TLRs

TLR agonists have shown to be effective agents in the treatment of several cancers. OK-432 as a ligand for TLR4 was used to treat gastric, cervical, and oral squamous cell carcinomas (Kikkawa et al., 1993; Maehara et al., 1994; Sato et al., 1997; Okamoto et al., 2006; Hironaka et al., 2006). Bacillus Calmette–Guérin (BCG) which has long been used in treatment of bladder cancer, is an effective stimulator of TLR2 and TLR4 signaling pathways (Tsuji et al., 2000; Uehori et al., 2005; Razack, 2007). LPS as a potent activator of TLR4, has been administered in phase II clinical trial to treat patients with colorectal and lung cancers (Otto et al., 1996). The agonists of TLR7 and TLR8 such as ssRNA and imiquimod were shown favorable results in the treatment of chronic lymphocytic leukemia and skin tumors (Scheel et al., 2006; Stockfleth et al., 2003; Spaner and Masellis, 2007). Administration of CPG as a ligand for TLR9 has been used to treat lymphoma, skin, brain, and renal cancers (Krieg, 2007; Carpentier et al., 2006).

TLR agonists are thought to promote anti-cancer immune responses through several ways. Their signaling cascade increases the recruitment of leukocytes particularly cytotoxic T, helper T, and NK cells which destruct tumors by the production of IFN- γ and cytotoxic mediators such as perforin. Besides, TLR signaling by up-regulation of the co-stimulatory molecules on APCs and stimulating the adaptive immune system plays an important role in raising anti-tumor responses (Rakoff-Nahoum and Medzhitov, 2009).

Pro-tumoral roles of TLRs

Chronic infection has been identified as the important factor involving in development of malignant neoplasms (Michelson et al., 2016). For instance, gastric cancer and colon cancer have been shown to be related with chronic *Helicobacter pylori* infection and chronic inflammatory bowel diseases, respectively (Kapetanakis et al., 2012).

The association between improper activation of TLRs and tumor progression is currently being investigated in several studies (Khajeh Alizadeh Attar et al., 2018). Up-regulation of NF κ B induced by inflammation has a central role in tumor development which explained in various malignancies including prostate cancer, hepatocarcinoma, myeloid leukemia, and multiple myeloma (Palayoor et al., 1999; Griffin, 2001).

TLR signaling leads to high production of pro-inflammatory cytokines such as TNF, IL-1, IL-6, and MCP-1, MIF, GRO chemokines by mediating NF κ B activation resulting in more infiltration of leukocytes to the infectious tissue. In this context, the production of anti-apoptotic factors provides a suitable milieu for promoting tumor growth (Philip et al., 2004).

In preclinical studies, the increased invasion, angiogenesis, and metastasis have been shown after LPS administration in mammary and colon adenocarcinomas models. Interestingly, TLR4 has shown to be required for growth of tumor cells in an

experimental murine model of colon adenocarcinoma in which tumor growth was stimulated by LPS. The proposed mechanism was the increased level of TNF and NF κ B activation in tumor cells which results in the up-regulation of anti-apoptotic proteins (Harmey et al., 2002; Luo et al., 2004).

Listeria monocytogenes has indicated to have a pro-tumoral role by activating TLR2 in ovary cancer cells via NF κ B stimulation. Infection with *Mycoplasma* is also associated with decreasing apoptosis and the promotion of tumor development by activation of TLR2 (Huang et al., 2007).

In cervical cancer, increased expression of TLR5 and TLR9 on the cervical epithelial cells was shown to be associated with cancer progression (Kim et al., 2008). The elevated levels of TLR9 were also found in lung and prostate cancer cells. In vitro stimulation of these cells with TLR9 ligands such as CpG-oligodeoxynucleotide or bacterial DNA was associated with tumor cell invasion (Droemann et al., 2005; Ilvesaro et al., 2007).

Besides, TLR interaction with DAMPs released from necrotic or damaged cells has shown to be associated with tumor development. Heat shock proteins (HSP60, HSP70), HMGB1 protein, ATP, Ca²⁺-modulating protein family (S100), and uric acid are the most important DAMPs stimulating tumor growth (Lotze et al., 2007; Ellerman et al., 2007). During oxidative stress, cytoplasmic organelles such as mitochondrial DNA could be released which interact with TLR9 and thereby activates its downstream signaling pathway leading to inflammation and tissue damage in tumor microenvironment (Oka et al., 2012).

Autoimmunity

Autoimmune disorders are characterized by various coincident mechanisms leading to decreasing immunological tolerance and uncontrolled activation of immune cells (Anders et al., 2005).

Growing body of evidence from human and animal models describes that dysregulation of TLR signaling contributes to the development of autoimmune disorders and tissue damage. Inappropriate TLR activation has shown to be associated with the pathogenesis of various autoimmune disorders including Systemic lupus erythematosus, Rheumatoid arthritis, Multiple Sclerosis, Scleroderma, and Sjogren's syndrome.

Systemic lupus erythematosus (SLE)

SLE is a systemic autoimmune disease identified by the production of autoantibodies against self-nuclear antigens resulting in the formation of immune complexes in serum of the patients. These complexes could stimulate TLR7 and TLR9 as the nucleic acid sensors especially on plasmacytoid dendritic cells leading to activation of both innate and adaptive immune responses.

Impaired clearance of apoptotic cells has been reported in patients with SLE. Accumulation of apoptotic debris would stimulate TLRs which subsequently lead to B cell activation and anti-nuclear antibody production.

The elevated level of serum IFN- α is found in SLE patients that plays an important role in disease progression and severity. IFN- α contributes to inducing the production of autoantibodies in these patients. As described earlier, the production of IFN- α could be a consequence of TLR7 and TLR9 signaling pathways (Horton and Farris, 2012).

Rheumatoid arthritis (RA)

RA is an inflammatory autoimmune disease characterized by the production of autoantibodies destructing joints. The increased expression of TLR2 and TLR4 has been found on peripheral blood monocytes in patients with RA. Besides, the elevated levels of both cell membrane- and endosomal-TLRs including TLR2, TLR3, TLR4, TLR7 have been shown in RA synovial tissues. The endogenous TLR ligands such as released RNA from necrotic synovial fluid cells cause the activation of TLR3 in synovial fibroblasts. An acute phase protein, serum amyloid A, has been identified in the peripheral blood of RA patients which acts as a TLR2 ligand.

Damage associated molecular patterns including HSPs (HSP60, HSP70, HSP22), HMGB1, fibrinogen, fibronectin, and hyaluronic acid fragments can activate TLR4 signaling pathway in rheumatoid synovium. Increased level of hyaluronic acid fragments in RA synovial fluid by interaction with TLR4 activates myeloid dendritic cells (Huang and Pope, 2009).

Multiple sclerosis (MS)

MS is an autoimmune disorder that affects the central nervous system (CNS) leading to immune-related demyelination and damage to oligodendrocytes and neurons.

TLR2 is up-regulated on CNS endothelial cells, microglia, astrocytes and oligodendrocytes, peripheral blood, and in demyelinated lesions of the patients with MS. TLR4 is increased in the CSF mononuclear cells of MS patients. Endogenous ligands such as HMGB1 by activating TLR2 and TLR4 stimulate the production of inflammatory cytokines like IL-1, IL-6, IL-23, and IL-12. This process enhances the polarization of naive T cells into Th1 and Th17 cells; these cells subsequently promote leukocyte recruitment to CNS by the production of INF γ and IL17, respectively, which leads to neurons damage.

TLR3 is expressed on neurons, cerebral endothelial cells, microglia, astrocytes, and oligodendrocytes. Interestingly, TLR3 engagement on the normal astrocytes stimulates the production of anti-inflammatory cytokines such as IL-10, which have an important role in down-regulation of inflammation and regulation of homeostasis in the brain. In the MS patients, a TLR3 ligand known as stathmin was increased in astrocytes, microglia, and neurons, which has shown to have the neuroprotective role (Miranda-Hernandez and Baxter, 2013).

Systemic sclerosis (SSc)

SSc or scleroderma is a heterogeneous autoimmune disease affecting connective tissue characterized by vascular injury and ischemia of the skin. Tissue damage and inflammation leading to release the molecules which can initiate inflammatory signaling pathways by interaction with TLRs.

SSA and S100A7 have been identified as two known ligands for TLR2 in SSc patients. Interaction of SSA with TLR2 results in high production of IL-6 which plays an important role in fibrotic effects in dermal fibroblasts.

Involvement of TLR4 with ligands such as Tenascin-C, HMGB-1, hyaluronan, and fibronectin are also indicated in the patients with SSc leading to enhance the fibrotic process and tissue damage.

Besides, the role of intracellular TLRs including TLR3, TLR7, and TLR9 has been shown in disease progression of SSc patients (O'Reilly, 2018).

Psoriasis

Psoriasis is an autoimmune disorder affecting skin characterized by hyper-proliferation of the epidermis. Damaged skin cells release DAMPs such as ssRNA and dsRNA which lead to triggering inflammatory responses.

keratinocytes have shown to express TLRs 1, 2, 3, 5, 9 in psoriasis patients. Upon DAMP or PAMP ligation, keratinocytes can produce several pro-inflammatory cytokines such as TNF, IL-6, IL-1, IL8, IFN β , IL36, IL25, and CXCL10 which stimulate T cell activation.

Intriguingly, antimicrobial peptide LL37 produced during skin injury can make a complex with dsRNA. This complex interacts with TLR3 resulting in the production of IFN- β from keratinocytes and plasmacytoid DCs. LL37 is also interacts with ssRNA or DNA which subsequently recognized by TLR7 or TLR9 leading to the production of IFN- α (Sun et al., 2019; McInturff et al., 2005).

Sjogren's syndrome

Sjogren's syndrome (SS) is a systemic autoimmune disease affecting exocrine, lacrimal, and salivary glands. High expression and inappropriate signaling of TLRs are described in both salivary cells and peripheral blood mononuclear cells (PBMCs) of the patients with SS.

Although the precise ligands for activating TLRs in the context of SS are not described in detail, TLR2/TLR1 and TLR2/TLR6 heterodimers have shown to highly expressed in salivary gland epithelial cells and PBMCs derived from SS patients. In vitro stimulation of salivary epithelial cells derived from SS patients with TLR2 ligands resulted in NF κ B and IL-15 up-regulation. This process leads to NK generation, increased expression of immune-regulatory molecules including ICAM-1, CD40, and MHC-1 on epithelial cells resulting in increased inflammatory immune responses.

High expression of TLR4 is also reported in salivary glands which was associated with glandular inflammation. Besides, TLR3 expression mediates apoptosis and increased production of inflammatory cytokines in salivary gland cells in SS. Activation of TLR7, TLR8, and TLR9 causes immune dysregulation and increased production of IFN α cytokine (Kiripolsky and Kramer, 2018).

Brain disease

TLR signaling has shown in host defense against CNS microbial infection. Recent studies have also demonstrated the involvement of TLRs during neurogenesis in the absence of any infectious causes. These receptors contribute to CNS homeostasis, cellular differentiation, immune regulation, and tissue repair.

Various cells in CNS including microglia, neuron, astrocyte, and oligodendrocyte have shown to express distinct TLRs. Microglia in the CNS parenchyma, are the important innate immune cells which express all TLRs (TLR1–9) and respond to several infectious agents. Astrocytes express TLR2, 3, 9 and they are involved in inflammatory responses through the production of different chemokines. Oligodendrocytes have shown to express TLR2 and TLR3 which their expression appears to be associated with CNS repair process, immune response regulation, and gliosis. Neurons by expressing endogenous TLRs including TLR3, 7, 8, 9 play important roles in both physiological and pathological conditions.

Besides, in Alzheimer's disease, TLR2, 4, 5, 7, 9 have shown to be important in response to amyloid beta accumulation in this disease (Momtazmanesh et al., 2020). In bacterial infections and meningitis, TLR2, 4, 9 are necessary for triggering anti-bacterial immune responses. In viral infections, TLR3 and 9 are involved in anti-viral immunity and neuronal repair. TLR1, 2, and 9 are indicated to participate in immunity against parasite infections of the brain, although they also can worsen disease severity. In contrast to the protective role of TLRs, TLR2 and 4 are also implicated in stimulating neuronal damage (Hanke and Kielian, 2011).

Diabetes

Increasing evidence suggests the elevated levels of inflammatory biomarkers in diabetes which promote susceptibility to vascular complications. Several studies have shown that the higher expression of TLR2 and TLR4 in patients with diabetes is associated with increased inflammatory responses and production of inflammatory cytokines including IL-1 β , IL-6, TNF, MCP-1, and IP-10. These TLRs and their ligands such as HSP60 and HMGB1 are related to the progression of atherosclerosis in diabetes patients (Jialal and Kaur, 2012).

Cardiovascular disease

Paradoxical functions of TLRs have been shown in cardiovascular disorders. TLR2, 3, 4, 6 are expressed on cardiac myocytes. In contrast to the role of TLR2 in the apoptosis induction of cardiac myocytes, TLR4 contributes to attenuating the apoptosis of these cells. However, TLR2 and TLR4 targeting is shown to be effective in septic cardiomyopathy.

Atherosclerotic lesion expressed an increased level of TLR4 leading to high inflammatory cytokine production. Lipid oxidation which plays an important role in the formation of atherosclerotic plaques results in the production of HSPs which act as TLR4 ligands. Interestingly, Chlamydia pneumonia as a ligand for TLR4 is closely related to atherosclerosis (Moghimpour Bijani et al., 2012).

Nomenclature

aHUS	Atypical hemolytic uremic syndrome
AP	Alternative pathway
ARMG	Age-related macular degeneration
C1-INH	C1 esterase inhibitor
C1q, 2C1r, 2C1s	C1 complex
C2a	Small C2 cleavage fragment
C2b	Large C2 cleavage fragment-enzyme
C3(H ₂ O)	Thioester-hydrolyzed form of C3
C3bBb	Alternative pathway C3 convertase
C3bBbC3b	Alternative pathway C5 convertase
C3bBbP	Alternative pathway C3 convertase with properdin
C3G	C3 glomerulopathies
C4bC2b	LP/CP C3 convertase
C4bC2bC3b	LP/CP C5 convertase
C4BP	C4b binding protein
CCP	Complement control protein
CL	Collectins
CLU	Clusterin
CP	Classical pathway
CR1/CD35	Complement receptor type 1
CR2/CD21	Complement receptor type 2
CR1g	Complement receptor of the immunoglobulin family
CRP	C-reactive protein
CSMD1	CUB and sushi domains protein 1
DAF/CD55	Decay-accelerating factor
DAMP	Damage-associated molecular pattern
FB	Factor B
FD	Factor D
FH	Factor H
FHL-1	Factor H-like protein-1
FHR	Factor H-related protein
FI	Factor I
GAGs	Glycosaminoglycans
HMGB1	High mobility group box 1
IC	Immune complex
IgAN	IgA nephropathy
LP	Lectin pathway
MAC (C5b-9)	Membrane attack complex

MASP	MBL-Associated serine protease
MBL	Mannose-binding lectin
MCP/CD46	Membrane cofactor protein
MDSC	Myeloid-derived suppressor cells
MPGN	Membranoproliferative glomerulonephritis
P	Properdin
PAMP	Pathogen-associated molecular pattern
PNH	Paroxysmal nocturnal hemoglobinuria
PTX-3	Pentraxin 3
RCA	Regulators of complement activation
SCR	Short consensus repeat
SLE	Systemic lupus erythematosus
sMAC (sC5b-9)	Soluble MAC
TP	Terminal pathway
Vn	Vitronectin

Introduction

Within this article we will be learning about the overall functions of the complement system, including how the complement system is activated through three pathways (classical, lectin and alternative), how the enzymatic complexes that lead to complement activation and amplification are formed, how the membrane attack complex is formed, what the main consequences of normal complement function are, as well as what are the pathological consequences of defects in complement proteins, defects in complement regulatory proteins, and exacerbated activation of the complement system as a consequences of disease, even when complement proteins are normal.

The complement system is an ancient system for detecting danger and is a major component of the innate immune system. It comprises a group of more than 50 proteins and protein sub-fragments, which participate in a cascade-like activation process. It efficiently protects the host from pathogenic microorganisms, contributes to several housekeeping functions, including immune complex regulation, and represents an essential link between the innate and specific/adaptive immune system. For example, it is a major effector system for antibody-mediated killing and it affects cell-mediated immunity. In order for complement to carry out its normal functions, it needs to be tightly regulated.

The complement system can be activated through three pathways, the classical pathway (CP), the lectin pathway (LP) and the alternative pathway (AP). Each pathway is activated through different mechanisms and they all lead to the activation of a central component known as C3. C3 is present in the blood at about 1.2 mg/mL and is one of the most abundant proteins in blood. After C3 is activated, there are a series of events that occur in sequence, leading to several outcomes. The three best characterized consequences are: (a) direct killing of pathogens by the formation of a macromolecular complex that will insert itself into the membrane, leading to osmotic lysis of the cell; (b) the opsonization of pathogens by complement fragments that are formed during activation and bind to the surface on which complement is activating. These fragments make the pathogen surface more attractive to phagocytic cells for it to be taken up and destroyed; and (c) generation of small cleavage fragments of complement proteins that go into circulation and serve as chemoattractant molecules and increase vascular permeability, for effectively recruiting inflammatory and immunocompetent cells. Although these are the functions that are most commonly known about complement, it is actually very pleiotropic, resulting in a series of additional events including effects on adaptive cellular immune responses, participation in critical housekeeping functions that result in the efficient removal of dead and dying cells and clearance of immune complexes from circulation, among many other functions. Some examples of each of these functions are depicted in [Fig. 1](#), and throughout this article, several of these will be examined.

The liver is the major source of many complement proteins and their production increases significantly during an acute-phase response (3–50 fold). However, many complement proteins are either exclusively or mainly produced by a variety of immune cells, indicating the relevance of complement beyond the circulation, in local tissue microenvironments where these cells are found [reviewed in [Cortes et al. \(2013\)](#), [Hosszu et al. \(2012\)](#), and [Graier et al. \(2013\)](#)]. Complement components are largely secreted as inactive stable zymogens (enzyme precursors) and circulate widely through body fluids and tissues. Activation causes a precursor zymogen to be cleaved and become an enzymatically active serine protease. This enzyme will cleave and activate a different zymogen. Thus, it is a triggered enzyme cascade where each successive enzymatic cleavage causes amplification.

The complement components were named in the order of their discovery, not in the order of the reactions. In general, complement cleavage fragments are designated with letters according to their relative size, with “a” fragments smaller than “b” fragments. The standard nomenclature used in this article has been reviewed elsewhere ([Kemper et al., 2014](#); [Bohlson et al., 2019](#)) and will follow that recommended by the Boards of International Complement Society and the European Complement Network.

Fig. 1 Pleiotropic functions of the complement system. The complement system participates in several processes including adaptive immunity, defense against pathogens, host homeostasis or “housekeeping functions”, and inflammatory processes.

Biomedical relevance of the complement system

Deficiency in complement cascade proteins leads to increased susceptibility to severe bacterial infections, development of systemic lupus erythematosus (SLE), immune complex disease, and other diseases. One of the most compelling clinical examples of how relevant the complement system is to the proper functioning of the whole immune system is a published case of a child with complete C3 deficiency (Channam et al., 2008). A 2-year-old boy had suffered from recurrent pyogenic infections (severe meningitis, pneumonia, otitis) since early infancy. He had undetectable total complement hemolytic activity (CH_{50} ; assay discussed in a later section) and C3 values in blood. Vaccination of the child did not lead to any long-term antibody response. *In vitro* development of immature dendritic cells and their maturation capacity was greatly impaired. Regulatory T cell development was also significantly impaired. Thus, complement is an essential component of the immune system.

Given all the essential functions, the complement system needs to be tightly regulated. The complement system is regulated at various levels and deficiencies in one or more complement regulatory proteins leads to pro-thrombotic hematological diseases, renal and ocular diseases, and others. Finally, under limited/normal activation conditions, complement activation leads to a transient increase in local inflammation or removal of damaged cells by phagocytosis. However, inflammatory diseases (e.g. ischemia/reperfusion, sepsis, asthma, arthritis, cardiovascular diseases, chronic transplant rejection, neurodegenerative disorders, etc.) usually overwhelm complement regulatory mechanisms and lead to pathologic, excessive inflammation and complement-mediated tissue damage. Functions of complement and diseases related to malfunctions in the complement system or to excessive complement activation will be discussed later in this article.

Historical background

Complement was first described more than 124 years ago, and since then, components of each pathway (alternative, classical, and lectin) and the pleiotropic functions of complement in innate and adaptive immunity have been elucidated. Detailed information about the origin of complement can be found in (Pillemer, 1943; Lachmann, 2006). In summary, in the late 1800s it was determined that blood serum was able to destroy bacteria and that this effect is thermosensitive. At the end of the 1800s and early 1900s it became clear that efficient destruction of pathogens by serum required the presence of a heat-stable substance, later called hemolysin and now known as antibodies, and a heat-sensitive component that “complemented” the role of antibodies, now called the complement CP. The biochemical characterization of the complement system began in the early 1900s. During the 1950s, the first evidences of an “alternative” pathway (AP) capable of activating the complement system on surfaces, without the presence of antibodies, emerged. During the 1950s–70s the characterization and order of the components improved substantially due to the improvement of chromatographic and electrophoretic procedures. Further purification of AP and CP proteins occurred and some complement deficiencies and disease phenotypes were described. The 1980s and 1990s were marked by the discovery of several other regulatory components and their ligands, genome sequences of complement components, and characterization of the thioester bond in C3 and C4. In the 1990s, discoveries included characterization of complement genes and protein domain-based identification of families of complement proteins and their structural characterization via NMR and X-ray

crystallography. From 1990 to now, the LP was discovered, as well as the interrelationship between complement and the coagulation system, and therapeutic targeting of complement function has taken place. The pleiotropic functions of complement effects on adaptive immunity and diseases, including more detailed description of mechanisms of action of complement regulatory proteins in diseases and non-canonical functions of certain complement proteins, has dominated the field thus far in this century.

Pathways of the complement system

Overview

Each of the three pathways of the complement system will be described in detail, first up to the point of the generation of the C5 convertase for each pathway, followed by the non-enzymatic assembly of the membrane attack complex (MAC), which is common for all three pathways. While the CP and LP rely on an initiating recognition molecule for activation, the AP does not require this and is constitutively active, relying mainly on the characteristics of the surface to allow activation to proceed.

Classical pathway (CP)

The CP (Fig. 2) is an antibody-dependent and -independent way of recognizing “danger” (e.g. pathogens, apoptotic self-cells).

Antibody-dependent activation of the CP and formation of the C3 and C5 convertases

When antigens on a surface, such as a pathogen surface, are recognized by antibodies, these antibodies can be recognized by the C1 protein of the CP. C1 is a complex of three different proteins, C1q, C1r and C1s. C1q is produced mainly by immature dendritic

Fig. 2 Overview of the complement system. Complement is activated by three pathways: the alternative, classical, and lectin pathways. The alternative pathway (AP) initiates when soluble C3 hydrolyzes to C3(H₂O). This conformational change allows Factor B (FB) to bind, which subsequently recruits Factor D (FD). FD cleaves FB to form Bb and Ba, resulting in the fluid phase AP C3 convertase, C3(H₂O)Bb. C3(H₂O)Bb cleaves C3 to C3a and C3b, and C3b covalently attaches to nearby surfaces to form the AP membrane-bound C3 convertase, C3bBb. The classical pathway (CP) initiates when the C1 complex (C1q, C1r, C1s) recognizes surface-bound immunoglobulins, circulating immune complexes, or pentraxins (not shown here). The activation of the C1 complex results in cleavage of C4 to form C4b and C4a, whereby C4b covalently attaches to cell surfaces, followed by cleavage of C2 to form C2b and C2a, forming the surface bound C3 convertase, C4bC2b. The lectin pathway (LP) initiates when mannose-binding lectin (MBL), Ficolins, or collectins recognize molecular patterns (i.e. carbohydrates) on foreign surfaces. Activated MBL-associated serine proteases are able to cleave C4 and C2, to form the C3 convertase, C4bC2b, similar to the CP. C3 convertases derived from all pathways cleave C3 to C3a and C3b. C3b generated by C3 convertases binds to or near the CP/LP C3 convertase to form a C5 convertase (C4bC2bC3b) or binds to or near the AP C3 convertase to form an AP C5 convertase (C3bBbC3b_n). C5 convertases cleave C5 to C5b and C5a to initiate the common terminal pathway, which culminates in the formation of the membrane attack complex (MAC or C5b-9). C3b produced from the cleavage of C3 by C3 convertases from all pathways forms an amplification loop that contributes to the generation of additional AP C3 convertases. Properdin (P) binds to AP convertases, significantly increasing the convertase half-life, leading to more efficient C3b deposition on cells surfaces.

cells, monocytes, and macrophages (Chai et al., 2007) and consists of six triple helical strands, each composed of three polypeptide chains (A chain, B chain and C chain) arranged in a hexameric structure that resembles an up-side-down bunch of tulips. The stalks are formed by N-terminal collagen-like sequences, while the globular heads are formed by the C-terminal portion of the chains. These globular heads at the end of each arm are the contact regions for the CH₂ region in the Fc region (constant region) of immunoglobulins. C1r and C1s are serine proteases that form a Ca⁺⁺-dependent tetramer composed of two C1r and two C1s molecules (C1s-C1r-C1r-C1s), that bind to C1q, also in a Ca⁺⁺-dependent manner, to form the C1 complex (C1q, 2C1r, 2C1s) (Fig. 3).

C1q must bind two or more immunoglobulin Fc portions to initiate the CP (Fig. 4). These Fc regions need to be at a critical distance from each other (<40 nm) in order to properly engage the C1q globular heads, explaining why soluble individual IgG do not activate C1 in circulation. In order of preference, C1 binds to IgM, IgG3, IgG1, and IgG2. IgE, IgG4, and IgD do not activate C1. The Fc portions of soluble pentameric IgM are normally not accessible to C1; however, when IgM binds to antigens on a surface, it changes its conformation (from planar to staple-like) in a way that exposes the CH₂ regions for binding to C1.

Once C1q binds to the Ig on the surface (recognition step), its structure is slightly modified, leading to sequential activation of C1r and C1s serine proteases. Activated C1s cleaves C4 into C4a and C4b. C4b exposes a reactive thioester site that, if close enough to the surface, allows it to bind covalently to the membrane via hydroxyl and amino groups present on carbohydrates and proteins, respectively. C4b that is not close enough to a surface is quickly inactivated by hydrolysis of the thioester site. C1s also cleaves C2 into C2a (small fragment) and C2b. C2b will bind in a Mg⁺⁺-dependent manner to the C4b that is on the cell surface, forming C4bC2b, which is the C3 convertase of the CP. It is important to note that some resources reverse the nomenclature for the C2 fragments, where the smaller fragment is referred to as C2b and the larger fragment as C2a. The standard nomenclature for C2 has not been agreed upon by the international community (Bohlson et al., 2019). Herein, we will use the more simple nomenclature, whereby C2b is the larger fragment. Within the C4bC2b convertase, the C2b fragment contains the proteolytically active site. C4bC2b cleaves C3, generating C3a (anaphylatoxin; chemotactic; to be discussed in a later section) and C3b. Proteolytic cleavage of the C3 α chain exposes a highly reactive thioester site in C3b, which is exposed and susceptible to nucleophilic attack by nitrogen or oxygen atoms (Fig. 5). These interactions result in the formation of covalent bonds with proteins (amino, -NH₂) or carbohydrates (-OH) if the C3b is close enough to the cell surface. If C3 is not close enough to bind, the activated thioester is quickly hydrolyzed and the C3b is inactivated. Approximately 90% of the C3b or C4b binds a water molecule, and becomes inactive and unable to bind within ~60 microseconds, avoiding unnecessary damage to nearby bystander surfaces. C4 is structurally homologous to C3 and has an identical thioester group.

Each C4bC2b convertase can cleave several C3 molecules, leading to opsonization of the surface. When a generated C3b binds to the C4bC2b convertase, it now forms part of a C4bC2bC3b complex, known as the C5 convertase of the CP. The C5 convertase will cleave circulating C5 into C5a (a small, soluble, pro-inflammatory fragment; to be explained in a later section) and C5b that will be the starting point for the assembly of the MAC (to be discussed in a later section).

Fig. 3 C1 complex and its role in classical pathway activation. The C1 complex (C1q, 2C1r, 2C1s) is the first component of the classical complement pathway and is composed of six C1q subunits, two C1r units, and two C1s units. C1q binds through its globular heads to antigen-antibody complexes. The globular heads of C1q are mainly responsible for target recognition, and specifically recognize the Fc region (constant region) of IgG or IgM bound to cells surfaces, but also bind bacterial and viral surface proteins, apoptotic cells, pentraxins, amyloid, and prion proteins. The collagenous tail mediates immune effector mechanisms, including complement action through interaction with the C1r and C1s proteases. Binding of C1q to immunoglobulins leads to conformational changes in the collagenous tail of C1q, which activates the associated serine proteases, C1r, which then cleaves the C1s molecules. Activated C1s then cleaves C4 into C4a and C4b and C2 into C2a and C2b, forming the CP C3 convertase (C4bC2b complex) (Fig. 2).

Fig. 4 Classical pathway activation vs no activation. A single pentameric IgM molecule has the potential to provide multiple binding sites for C1q and activate C1 to initiate the CP. However, soluble IgM has a planar conformation (top left panel), which does not allow C1 complex to bind. Once a single IgM binds its targets (top right panel), it undergoes a conformational change (staple form) in the constant region of immunoglobulins, exposing the C1 binding sites on IgM. In contrast, a single IgG cannot bind a C1 complex in the fluid phase (bottom left panel) nor when bound to cell surfaces unless several bound IgGs bound are close enough to be recognized by C1 (bottom right panel).

Antibody-independent activation of the CP

As mentioned above, the CP can also be initiated by antibody-independent mechanisms. C1 also recognizes many different target molecules on the cell walls and membranes of microorganisms and fragments of cellular and sub cellular membranes, including surface-bound pentraxins such as C-reactive protein (CRP) and pentraxin 3 (PTX-3), the damage-associated molecular pattern (DAMP) HMGB1 (Kishore et al., 2004; Merle et al., 2015a), phosphatidyl serine, DNA, certain annexins, among other ligands on dead and dying cells [reviewed in Merle et al. (2015a) and Galvan et al. (2012)], and LPS (Roumenina et al., 2008) and bacterial porins (Alberici et al., 1996). C1 binding to these ligands leads to C1 activation and CP activity.

Lectin pathway (LP)

The LP is very similar to the CP, but differs in the recognition molecules that initiate the pathway (Fig. 2). The LP relies on antibody-independent recognition of “danger” (sugar residue patterns), by mannan binding lectin (MBL), Ficolins (M, L, H, also known as 1, 2, and 3, respectively) and collectin CL-LK (heterodimer of CL-L1 and CL-K1) present on bacteria, viruses, and dead/dying cells (Kjaer et al., 2013; Matsushita et al., 2013). The LP can also be triggered by the DAMP HMGB1 (Ratajczak et al., 2019).

Although structurally similar to C1q, MBL, Ficolins, and CL-LK are instead collectins (collagen-like domain and a carbohydrate-binding domain). MBL binds specifically to mannose and certain sugars that form distinctive patterns on microbial surfaces and it must bind multiple sugars to activate. Ficolins and MBL are very similar structurally; although their carbohydrate-binding moieties are different. MBL recognizes glucose, mannose, and *N*-acetyl-glucosamine, Ficolins have a lectin activity toward *N*-acetylglucosamine through their fibrinogen-like domains, and CL-LK binds mannose-containing carbohydrates. MBL is formed by 3–6 oligomers of trimeric subunits, Ficolins form homooligomers of 4–6 trimeric subunits, and CL-LK is a

Fig. 5 Complement system targets cells surfaces. C3 has an intact internal thioester bond which is formed between cysteine and glutamic acid residues found in the α -chain of C3. When C3 or C4 (not shown in this figure) are cleaved during the process of complement activation, the thioester bond becomes reactive (activated thioester), which is quickly hydrolyzed in the fluid phase forming inactive C3b or attaches to surfaces by forming ester or amide bonds (or transacylated thioester bond) with carbohydrates or proteins found on surfaces.

heteromeric complex between CL-L1 and CL-K1 [reviewed in Cedzyński et al. (2018), Matsushita (2018), and Ohtani and Wakamiya (2018)]. MBL, the Ficolins, and CL-LK form a Ca^{++} -dependent complex with homodimers of two serine proteases, MASP-1 and MASP-2 (related to C1r and C1s) and can also associate with MASP-3. The MASP acronym stands for mannan binding lectin-associated serine protease. Once MBL, Ficolins or CL-LK are bound to a surface, MASP-1 activates MASP-2 or MASP-2 autoactivates (Héja et al., 2012; Endo et al., 2015; Hansen et al., 2016). MASP-1 and MASP-2 cleave C2, while MASP-2 also cleaves C4 (Takahashi et al., 2008). The role of MASP-3 within the LP remains undefined; however, it does have a function within the AP, which will be discussed in the next section. All steps of the LP after cleavage of C4 are identical between the CP and LP, including having identical C3 and C5 convertases (C4bC2b and C4bC2bC3b, respectively).

Alternative pathway (AP)

Activation of the AP and formation of the C3 convertase

The AP is the first to appear in evolution (most ancient of all the pathways) and is distinct from the CP and LP with regard to how it activates. Unlike the CP and LP, the AP does not require a recognition molecule to activate. It is active by default and will only effectively activate and amplify on surfaces that “allow it to” due to the lack of negative regulation of the AP on that surface. In simple terms, if C3b lands on a surface that has the ability to regulate complement, activation will not proceed. Conversely, if C3b lands on a surface without regulators, activation will proceed uncontrolled. So where does the C3b that lands on the surface come from and how is the AP regulated? These are the key questions to answer in order to understand the AP (Figs. 2 and 6). Spontaneous cleavage of C3 is postulated to occur at a low but constant rate in blood (Pangburn et al., 1981; Lachmann et al., 2018), and is known as tickover phenomena. In order for this to occur, C3, undergoes spontaneous hydrolysis at a low rate, where water is introduced in the thioester site of uncleaved C3. The hydrolyzed C3 in blood is known as C3(H₂O). The hydrolysis of soluble C3, changes the structure of C3 in such a way that C3(H₂O) can now bind Factor B (FB) in a Mg^{++} -dependent manner. Once FB binds to C3(H₂O) it can be cleaved by mature Factor D (FD) into a smaller fragment known as Ba (with no known function) and a larger fragment Bb that remains bound to the C3(H₂O), generating C3(H₂O)Bb. In order for FD to be able to cleave FB, MASP-3 (introduced in the previous section) must cleave zymogenic pro-FD to generate mature FD (Fig. 6). Thus, MASP-3 serves as a bridge between the LP and the AP (Takahashi et al., 2010; Dobó et al., 2016). C3(H₂O)Bb is the soluble C3 convertase of the AP that, via its enzymatic site (Bb), cleaves C3 into C3a (pro-inflammatory, chemoattractant molecule) and C3b. If the C3b is close enough to the membrane, it will bind covalently to the membrane or be quickly inactivated by hydrolysis in the same way as described for the CP and LP. The C3b that does bind to the surface is structurally similar to the intermediate form of C3 [C3(H₂O)] and thus C3b on the surface (Fig. 6) can also bind FB, which will be cleaved by mature FD into a smaller fragment known as Ba that is released into the fluid phase and a larger fragment Bb that remains bound to the C3b. This C3bBb complex is known as the membrane-bound C3 convertase of the AP. This convertase cleaves C3 into C3a and C3b, and if the C3b is close enough to the membrane it will bind covalently to it, as described in Fig. 5.

It is important to note that there are other ways in which the AP can activate (in addition to tickover), including (a) generation of C3(H₂O) via contact activation [reviewed in Nilsson and Nilsson Ekdahl (2012)]; (b) C3b and C3(H₂O) may bind directly to certain cell surfaces via P-selectin, CR2 and/or other ligands, some unknown (Saggu et al., 2013; Hamad et al., 2010; Merle et al.,

Fig. 6 Alternative pathway activation on pathogen or altered self surfaces. Spontaneous hydrolysis of C3 induces a conformational change of C3, forming C3(H₂O). Factor B (FB) binds to C3(H₂O) and subsequently Factor D (FD) cleaves FB into Bb and Ba, forming the soluble AP C3 convertase, C3(H₂O)Bb. This convertase can cleave soluble C3 leading to deposition of C3b on targeted surfaces and production of C3a, a small pro-inflammatory molecule that is released into solution. Since pathogen surfaces inefficiently recruit FH (see Fig. 7C), AP complement activation proceeds unchecked leading to formation of membrane bound C3 convertases (C3bBb), C5 convertases, and membrane attack complex (MAC or C5b-9) formation. Properdin (P), a positive regulator, assures efficient amplification of C3b deposition by increasing the half-life of AP C3 convertases.

2019; Mold et al., 1988); (c) LPS on cell walls of Gram negative bacteria, although *in vivo* relevance is uncertain [reviewed in Harboe and Mollnes (2008)]; and (d) the physiological forms properdin, a positive regulator of the AP (to be further discussed in a later section), can bind certain surfaces such as dying host cells and certain bacteria, and activate the AP by recruiting C3b and FB, forming a C3 convertase de novo, *in vitro* (Hourcade, 2006; Ferreira et al., 2010a). The *in vivo* relevance of this phenomena has been controversial due to methodological limitations that are discussed elsewhere (Ferreira et al., 2010a; Chen et al., 2018). One recent study supports the role of properdin as a possible DAMP recognition molecule *in vivo* indicating physiological properdin binds to proximal tubular cells in the kidney in a syndecan-1/heparan sulfate-dependent, but not C3-dependent manner (Lammerts et al., 2020).

Stabilization of the C3bBb convertase by properdin and amplification of the AP, CP and LP

In order for AP activation to occur fast due to efficient function of the C3 convertase (C3bBb), which is key for effective activation and amplification, C3bBb needs to interact with a blood protein known as properdin, forming C3bBbP (Fig. 6). The main function of properdin is to stabilize the AP convertases. When properdin binds to C3 convertases, it increases their half-life by 5–10-fold (Fearon and Austen, 1975; Schreiber et al., 1975), allowing effective cleavage of C3, surface opsonization, and amplification given the long half-life of the convertase. It is important to note that the C3b that lands on a surface due to CP and LP activation (Fig. 2) can serve as a starting point for the AP, thus amplifying each of those pathways. Amplification by the AP may account for up to 80% of the C5a and MAC generated by CP activation (Harboe et al., 2004). Additional information related to properdin will be discussed in later sections.

Generation of the C5 convertase of the AP

When there is one or more C3b fragments, generated by the C3 convertases, that land on or near a C3 convertase, this convertase shifts its affinity from C3 to C5, becoming a C5 convertase of the AP (C3bBbC3b; Fig. 2). In some texts the C5 convertase can be found as C3b_{2-n}Bb, where the "2-n" refers to 2 or more C3b molecules. The C3bBbC3b convertase is also stabilized by properdin, increasing its half-life ~10-fold (Fischer and Kazatchkine, 1983; Medicus et al., 1976). The C3bBbC3b convertase will cleave circulating C5 into C5a (a small, soluble, pro-inflammatory fragment; to be discussed in a later section) and C5b that will be the starting point for the assembly of the MAC (to be discussed in a later section).

How does the AP know when to activate?

As mentioned, the AP is always active by default, but activation only proceeds on surfaces that allow it to. Fig. 7A explains what this means in simple terms. C3b can land on a non-activating surface (e.g. host) or on an activating surface (i.e. pathogen or altered-self cell, such as a dead or dying cell). If C3b lands on a "non-activating" surface, it will be able to effectively regulate complement, and

Fig. 7 Alternative pathway activation on self vs non-self surfaces. (A) Panel representing the main differences between non-activating surfaces and activating surfaces. (B) Non-activating surfaces (host cells). Activation of AP is efficiently regulated by Factor H (FH). FH efficiently protects host surfaces when it binds to C3b and poly-anions (i.e. GAGs, sialic acid) found on non-activating surfaces. The consequences of recruiting FH to non-activating surfaces is an immediate shutdown of AP activation by both accelerating the decay of the AP C3 convertase, C3bBb, and recruiting Factor I (FI) to cleave C3b and inhibit the formation of the AP C3 convertases. (C) Activating surfaces. Pathogens (non-self) or altered cells surfaces do not allow efficient binding of FH, thus leading to formation of AP C3 convertases that promote abundant C3b deposition and formation of the membrane attack complex (MAC or C5b-9) on targeted surfaces. Eventually, FI cleaves C3b into iC3b and C3d that interact with specific receptors found on immune cells to promote phagocytosis and enhance immune responses.

thus the C3b will be immediately inactivated, no activation or amplification will occur, and there will be no complement-mediated damage. However, if C3b lands on an “activating” surface, there will be a lack of or inefficient regulation, which will result in complement-mediated opsonization with C3b and C3b sub-fragments that will serve as important ligands for specific receptors on immune cells, leading to phagocytosis and immune responses. In addition, the cascade will proceed to form membrane attack

complexes (MACs). One key example of a regulator for understanding what defines a surface as an activator or non-activator, is the ability of the negative complement regulator Factor H (FH) to discriminate between host/self (non-activating) and non-self/ altered-self (activating) surfaces (Fig. 7B). FH circulates at ~200–500 mg/mL in blood and has multiple binding sites for C3 fragments and polyanions [e.g. sialic acid and glycosaminoglycans (GAGs)] (Pangburn and Muller-Eberhard, 1978; Fearon, 1978; Meri and Pangburn, 1990; Ram et al., 1998; Kazatchkine et al., 1979; Blackmore et al., 1998; Pangburn et al., 2009; Haque et al., 2020). The non-activating surface needs to have both host markers (i.e. polyanions, which are present on most of our cells and tissues) as well as initial deposits of C3b in order to facilitate the binding of FH to the interface of both ligands simultaneously (Fig. 7B). The presence of both C3b and polyanions allows FH to bind with sufficient affinity and avidity to the surface in order to remain bound long enough to carry out its complement regulatory functions, which will be discussed in a later section. Briefly, these include (Fig. 7B): (a) Decay acceleration that consists in accelerating the decay of the C3 convertases by displacing the enzymatic portion of the C3bBb complex (Bb), and (b) Cofactor activity, in which FH acts as a cofactor for Factor I (FI)-mediated cleavage of C3b to iC3b, which can no longer bind FB to form new convertases. Thus, activation and amplification do not proceed and insignificant amounts of iC3b are left on the surface. In addition to the fluid phase regulator FH, host cells are also protected by membrane-bound complement regulatory proteins (e.g. CD55, CD59, MCP, CR1, etc.) that carry out decay acceleration, cofactor activity, and other functions. The LP and CP are also controlled by regulatory proteins; most are common to all pathways, while others are pathway specific. All regulatory proteins and their functions will be discussed in the next major section.

In the case of an “activating” surface, fast and efficient activation and amplification of the AP will occur because the initial C3b lands on a surface (such as a pathogen) where there are (a) no or low host polyanionic markers, leading to FH not being able to bind effectively fast enough due to lack of adequate affinity and avidity to the surface and (b) no or low amounts of membrane-bound regulatory proteins (Fig. 7C). This allows activation and amplification to proceed very quickly, unimpaired, leading to a surface that is covered with thousands of C3b fragments. These fragments, will lead to the formation of MACs or, over time, will be further cleaved into iC3b and then C3d/C3dg by a regulator known as FI with the help of cofactors, such as FH, and others. Thus, the surface will be decorated with a variety of thousands of opsonic C3 fragments that will play central roles in destruction by phagocytosis and in generating effective immune responses by interacting with specific receptors on immune cells (e.g. CR1, CR2, CR3, etc.). These receptors and their associated functions will be discussed in a later section. Most pathogens have “activating” surfaces and are cleared by complement-mediated lysis and/or phagocytosis. However, many pathogens have evolved the ability to make their own complement regulatory proteins or sequester host regulatory proteins, making their surfaces “non-activating” as a complement evasion strategy (further discussed in a later section).

Cleavage of C3 and C5 in a complement-independent manner

C3 and C5 can be cleaved in the absence of complement activation due to a cross-talk between the complement and coagulation pathways. An example of this is that the extrinsic pathway of the coagulation system involves proteases that have isolated convertase activity, including factor IXa, Xa, XIa, thrombin, and plasmin, which cleave C3 and C5 (Amara et al., 2010), and renin and kallikrein, which cleave C3 (Békássy et al., 2018; Irmischer et al., 2018).

Generation of the membrane attack complex (MAC)

Once the C5 convertase is formed in each pathway, the rest of the cascade is identical for all the pathways. Cleavage of C5 by the C5 convertases releases soluble C5b (and pro-inflammatory fragment C5a; to be discussed in later section). C5b binds C6 and C7 in the blood, which exposes a hydrophobic site on C7, leading to the binding of soluble C8. Binding of C8 to this complex exposes a hydrophobic site, allowing C8 to penetrate the membrane partially. The C5b-C8 complex promotes polymerization of C9, which completely penetrates the membrane, forming a membrane pore that leads to osmotic lysis of the cell. All reactions after C5b production are nonenzymatic (assembly). A MAC complex can have a wide range of C9 molecules (as many as 22). A fully formed MAC is an asymmetrical pore, where the polymerized C9 does not completely close and overlaps at the origin point (Serna et al., 2016). The MAC can also be sub-lytic, with a variety of functions other than cell lysis that include inducing proliferation, protein synthesis, and apoptosis, amongst others (Morgan, 2016). Regulation of MAC will be discussed in the next section and consequences of deficiencies in components that make up MAC will be discussed in a later section.

Regulation of the complement system

Overview

Regulation of all complement pathways is essential to protect the host from unwarranted complement-mediated attack. Deficiencies in any of these regulators will lead to a variety of disease pathologies, as will be discussed in a later section. There are several proteins that are essential in modulating and controlling complement activation on self surfaces. These regulators are considered negative or positive, depending on whether these factors reduce or promote complement activation on cell surfaces, respectively.

Most of negative regulators are members of a network of proteins known as regulators of complement activation (RCA), which includes CR1, DAF, MCP, C4BP, FH, FHL-1, CSMD1 and FH-related family proteins [reviewed in Hourcade et al. (1989) and Skerka et al. (2013)]. These RCAs are mainly composed of complement control protein (CCP) domains, also known as a short consensus

repeat (SCR) or sushi domains. Each domain consists of ~60 amino acids in size with four conserved cysteine residues in which the first and third and second and fourth residues are cross-linked. The number of CCPs varies from 2 to 37 depending on the regulatory protein (Barnum and Schein, 2018a). CRiG is the only complement regulatory protein that is not part of the RCA, but rather part of the immunoglobulin family (Langnaese et al., 2000; Helmy et al., 2006). All the RCA proteins are able to control complement activation by either binding to proteolytic fragments of C3 and C4, or serve as cofactors in their degradation, or by inhibiting their biological activities (Alcorlo et al., 2015). Another complement regulator, C1-esterase inhibitor (C1-INH), which belongs to the serpin family, regulates the initial steps of the AP and LP pathways. Another subset of regulators includes those that inhibit the terminal pathway or the formation of the MAC, either on cell surfaces or in the fluid phase, and share no structural homology (i.e. CD59, clusterin, vitronectin) (Zipfel and Skerka, 2009). Finally, there is a small group that are considered positive regulators that promote C3b deposition on cell surfaces (i.e. properdin and possibly FH-related proteins) (Fearon and Austen, 1975; Schreiber et al., 1975; Jozsi et al., 2019). The regulators of complement are explained below and summarized in Table 1.

Negative regulation of the complement system

Inhibition of C1, MBL, and Ficolins

C1-INH is a multiple-function serine protease inhibitor, regulator of several plasma cascade systems, such as the CP of the complement system and the plasma bradykinin-forming cascade [reviewed in Davis (1988) and Beinrohr et al. (2008)]. C1-INH has an anti-inflammatory function via the irreversible displacement of complement serum proteases C1r and C1s from C1q in the CP pathway, and displacement of MASP2 from MBL or Ficolins from the LP (Fig. 8A and Table 1). C1-INH has non-complement-related functions such as controlling vascular permeability by inhibiting factor XIIa and plasma kallikrein, which are involved in the formation of bradykinin, a potent vasodilator molecule. Other possible functions of C1-INH include the role of inhibiting factor XIa, representing the initial protease of the intrinsic pathway of coagulation, the fibrinolytic proteases plasmin, and interacting with immune cells (neutrophils and macrophages) and enhancing phagocytosis [reviewed in Drouet et al. (2018), Zeerleder and Levi (2016), Davis et al. (2010), Liu et al. (2007), and Liu et al. (2003)].

Decay acceleration

The regulatory proteins that have decay acceleration function will “dismantle” the C3 and C5 convertases, thus inhibiting the cleavage of C3 and C5 (Gigli et al., 1979; Pangburn and Müller-Eberhard, 1986; Nicholson-Weller et al., 1982; Medof et al., 1984; Pangburn, 1986; Fujita et al., 1987). Specifically, decay acceleration protects host cells from complement-mediated attack by preventing the formation of, as well as accelerating the decay of, the CP/LP and AP C3 and C5 convertases (Fig. 8B and Table 1). During decay acceleration, the regulator either (a) competes for FB or C2b binding to C3b or C4b, respectively, impairing the formation of the convertase, or (b) displaces the enzymatic portion of the convertase (Bb for the AP and C2b for the CP), effectively shortening the half-life of the convertase. Circulating soluble negative regulators, FH and C4 binding protein (C4BP), have decay accelerating activity on the cell surface mainly for the AP and CP, respectively. FH also is an essential regulator of the fluid-phase AP convertase C3(H₂O)Bb. Membrane-bound complement negative regulators with decay accelerating activities in both the CP/LP and AP pathways include complement receptor 1 (CR1/CD35), decay accelerating factor (DAF/CD55), membrane cofactor protein (MCP/CD46) and soluble FH-like protein 1 (FHL-1) (Kühn et al., 1995).

Cofactor activity

FI plays a fundamental role in protecting host cells from complement-mediated attack by quickly cleaving the α' -chains of newly formed membrane-bound C4b and C3b, generating so-called “inactive” forms of C3b (iC3b) and C4b (iC4b). The iC3b and iC4b molecules remain bound to the cell and can no longer bind FB or C2b, respectively. Thus, C3 convertases can no longer be formed, inhibiting all complement pathways. This FI regulatory function can only be accomplished in the presence of a cofactor, including FH, CD46, CR1, C4BP, or CSMD1 (CUB and sushi domains protein 1) (Roversi et al., 2011; Nilsson et al., 2011; Whaley and Ruddy, 1976; Pangburn et al., 1977; Harrison and Lachmann, 1980) (Fig. 8C and Table 1). FI also plays a central role, using FH as a cofactor, in cleaving fluid phase C3(H₂O) to iC3(H₂O), thus also regulating fluid phase complement activity.

As initially mentioned in a previous section, a surface on which complement has successfully activated (such as on pathogens) will be covered in several thousand C3b molecules, which will be converted to iC3b, and C3dg molecules by FI with the help of cofactors (Fig. 7C), as mentioned above. These iC3b and C3dg fragments will be recognized by specific receptors on immune cells promoting phagocytosis and adaptive immunity (van Lookeren Campagne et al., 2007; Carroll and Isenman, 2012). These receptors and their associated functions will be described in the next major section.

Inhibition of the terminal pathway (MAC)

Inhibition of MAC (C5b-9) formation is an essential step that assures host cells are protected from complement-mediated lysis. Fig. 8E illustrates a subset of regulators that inhibit the formation of the MAC either on cell surfaces (CD59) or in the fluid phase (clusterin, vitronectin). CD59 inhibits the polymerization of C9, while Clusterin and Vitronectin inhibit soluble C5b-7 and/or soluble C5b-9 (sMAC), from binding to the cell surface (Zipfel and Skerka, 2009).

Table 1 Summary of complement regulatory proteins and associated functions.

		<i>Name (symbol)</i>	<i>Concentration in serum and MW</i>	<i>Role in the regulation of complement system^a</i>
Negative regulators	Fluid phase complement regulatory proteins	C1 inhibitor (C1-INH)	0.15–0.30 mg/mL Predicted: 52.9 kDa, 71.1 kDa (glycosylated)	Dismantles C1, MBL and Ficolins complexes by removing C1r and C1s from C1q and MASP-2 from MBL and Ficolins, respectively. Inhibits Factor XIIa and plasma kallikrein of the contact system. Essential for control of bradykinin generation.
		C4-binding protein (C4BP)	200 µg/mL 500 kDa (oligomeric glycoprotein)	Binds C4b, displacing C2b; cofactor for C4b cleavage by Factor I.
		Factor H (FH)	0.3–0.5 mg/mL 155 kDa	Main regulator of the fluid phase AP convertase C3b(H ₂ O)Bb, by displacing Bb from C3b(H ₂ O). Regulates the cell-bound AP convertases by (a) binding to a combination of C3b and polyanions on surfaces and competing with binding of FB to C3b and/or displacing Bb from C3b and (b) acting as a cofactor for C3b cleavage by Factor I.
		Factor I (FI)	~35 µg/mL Predicted: 65–75 kDa	Serine protease that cleaves C3b and C4b to generate iC3b, C3d/dg, or iC4b, C4d; aided by cofactors Factor H, MCP/CD46, C4BP, or CR1/CD35.
		Factor H like protein-1 (FHL-1)	30–50 µg/mL Predicted: 49 kDa	Regulates the fluid phase AP convertase C3b(H ₂ O)Bb by displacing Bb from C3(H ₂ O). FHL-1 also has Factor I-cofactor activity.
	Membrane bound complement regulatory proteins	Complement receptor 1 (CR1/CD35)	Predicted depending of allotypes: 190–280 kDa	Displaces Bb from C3b and C2b from C4b. Cofactor for C4b and C3b cleavage by Factor I.
		Complement receptor of the immunoglobulin family (CRiG)	Predicted: 42 kDa	Cofactor for C3b cleavage by Factor I.
		Decay-accelerating factor (DAF/CD55)	Observed: 70 kDa	Displaces Bb from C3b and C2b from C4b.
		Membrane Cofactor proteins (MCP/CD46)	Predicted: 39 kDa	Cofactor for C4b and C3b cleavage by Factor I.
		CUB and sushi domains protein 1 (CSMD1)	389 kDa	Cofactor for C3b cleavage by Factor I.
Positive regulators	Fluid phase complement regulatory proteins	Properdin (P)	5–15 µg/mL Predicted 53 kDa	Binds C3b and Factor B or Bb and stabilizes the alternative pathway C3 and C5 convertases.
		Factor H related -1, -4, -5 (FHR-1, -4, -5)	CFHR1: 35.7 kDa, CFHR2 25.9 kDa, CFHR3 35.5 kDa, CFHR4A: 63.4 kDa, CFHR4B: 35.3 kDa, CFHR5: 62.5 kDa Predicted 8.96 kDa	CFH-1, -4, -5 compete with Factor H, acting as potential positive regulators of the AP. All FHR interact with C3b, C3d/dg and iC3b.
Terminal pathway inhibition	Membrane bound complement regulatory protein	CD59	Predicted 8.96 kDa	CD59 inhibits the formation of MAC by locking onto C8 in the forming MAC to block the recruitment of C9 into the complex.
	Fluid phase complement regulatory proteins	Mature form of clusterin (sCLU)	22.6–87.2 µg/mL 70–85 kDa	Binds to a structural motif common to C7, C8 and C9β inhibiting the correct complex assembly and prevents their insertion into cell membranes.
		Vitronectin (Vn)	200–400 µg/mL Predicted: 52.5 kDa	Binds to pre-membrane attack complex (C5b-7); hinders the insertion of C5b-7 into the cell membrane, inhibiting C9 to form part of the MAC. Interacts with soluble C5b-7, C5b-8 and C5b-9, in which sC5b-7 further attracts free C8 and C9 to form the sC5b-8 and sC5b-9, respectively.

A. C1 Inhibitor

B. Decay Accelerating Activity

C. Cofactor Activity

D. Properdin

E. MAC Inhibition

Fig. 8 Function of complement regulatory proteins. (A) C1 inhibitor function. C1 and MBL complexes are able to cleave C4 and C2 to generate the CP/LP C3 convertase, C4bC2b (left side of panel). C1-inhibitor (C1-INH) prevents complement activation by removing the serine proteases C1r, C1s, or MASPs from C1 and MBL complexes, respectively. (B) Decay accelerating activity. Several factors including DAF/CD55, CR1/CD35, and Factor H (FH) are able to displace Bb from the AP C3 convertase, C3bBb, while DAF/CD55, CR1/CD35, and C4BP displace C2b from the CP/LP C3 convertase, C4bC2b. (C) Cofactor activity. MCP/CD46 and CR1 act as cofactors for Factor I (FI)-mediated cleavage of C3b into iC3b, and C4b into iC4b. FH acts as a cofactor for FI-mediated cleavage of C3b into iC3b, while C4BP acts as a cofactor for FI-mediated cleavage of C4b into iC4b. CR1 can also act as a cofactor for FI to further cleave iC3b and iC4b into C3dg and C4d, respectively. Inactivated fragments, iC3b and iC4b, are no longer able to form C3 convertases. (D) Properdin function. AP C3 convertase, C3bBb, cleaves C3 into C3a and C3b. Properdin (P) is a positive complement regulator that stabilizes the AP C3 convertases increasing 10 times its half-life to promote efficient C3b deposition. (E) MAC inhibitor. C5 is cleaved by all C5 convertases to generate C5a and C5b. C5b is the focal point for the formation of the pore-forming membrane attack complex (MAC or C5b-9). CD59 inhibits the formation of MAC by binding to C8 and inhibiting the polymerization of C9 in the bilayer membrane of cell surfaces. Clusterin (CLU) and Vitronectin (Vn) bind soluble MAC (sMAC) to inhibit its deposition on cells surfaces. CLU also can bind to soluble C5b-7 (sC5b-7) and inhibit its binding to cells membranes.

Inactivation of C5a, C3a

During complement activation, C3 and C5 are cleaved, releasing small soluble fragments known as C3a and C5a, respectively. These molecules are pro-inflammatory and carry out several key functions (to be discussed in the next major section). In order to restrict the action of these potent molecules close to where they are synthesized, plasma carboxypeptidases N and R remove the C-terminal arginine from the C5a and C3a peptide forming the C5a desArg and C3a desArg derivatives (Matthews et al., 2004; Mueller-Ortiz et al., 2009).

Positive regulation of the complement system

Properdin

AP C3 convertases have a short half-life of ~90 s, under physiological conditions, in the fluid phase and on cell surfaces (Pangburn and Müller-Eberhard, 1986). Properdin is a 53 kDa plasma glycoprotein that has the main function of binding to and stabilizing surface-bound AP C3 convertases (C3bBb) and C5 convertases (C3bBbC3b) by extending the half-life of the nascent convertases 5–10-fold, leading to accelerated and efficient amplification of C3b deposition on surfaces (Fig. 8D) (Berends et al., 2015; Fearon and Austen, 1975; Schreiber et al., 1975). Properdin is found at 4–25 µg/mL in plasma and each monomer is composed of seven thrombospondin repeat (TSR) type 1 domains that, under physiological conditions, form mainly cyclic dimers (P2; parallel strand shaped), trimers (P3; triangle shaped) and tetramers (P4; square shaped) in an approximate 1:2:1 ratio via head-to-tail association of its identical monomers (Pangburn, 1989; Smith et al., 1984). The convertase-stabilizing activity of the P4 is greater than the P3, and both are greater than the P2 (Pangburn, 1989; Blatt et al., 2016b). The vertices of the oligomers interact with both C3b and FB in the convertases (Alcorlo et al., 2013; Pedersen et al., 2017), helping explain why the oligomers vary in functional potency. Properdin is synthesized by various pro-inflammatory cell types, including activated neutrophils, monocytes, and T cells and is thus important for regulating complement in local cellular microenvironments. Finally, deficiency in properdin leads to increased susceptibility to fulminant systemic Neisserial infections (to be discussed in a later section).

FHR proteins

In humans, there are five FH-related (FHR1-5) proteins, whose functions are not completely characterized. However, studies support a role for some FHRs that is the opposite of the role of FH and FHL-1. Specifically, they enhance complement activation by competing with the FH and FHL-1 [reviewed in Cserhalmi et al. (2019) and Harrison (2018)]. The magnitude of their physiological effects as positive regulators *in vivo* remains to be determined.

Functions of complement and associated receptors

Overview

The complement system is highly pleiotropic and aside from generating MACs on surfaces to induce direct osmotic lysis, several opsonic fragments (i.e. C3b, C4b, iC3b, C3d/dg) and pro-inflammatory mediators (e.g. C3a, C5a) are generated, which need to interact with specific receptors on a variety of cells in order to carry out their functions. In addition, certain intact complement proteins, such as C1q and others, also bind specific receptors, leading to essential functions. In this section, some critical roles of complement will be discussed, and, when applicable, explained in the context of the receptors that are required for a particular function.

Functions associated with killing of pathogens

Direct killing via MAC

The main role of MAC is to kill certain gram-negative bacteria that cannot be efficiently removed by opsonophagocytosis. Examples of bacteria that require MAC formation on their surface for elimination are *Neisseria*, *Haemophilus*, *Moraxella*, and others [reviewed in Morgan et al. (2017)]. Deficiencies in MAC components leave individuals highly susceptible to disseminated Neisserial infections, as will be discussed in a later section. Susceptibility to MAC varies widely among Gram-negative bacteria (i.e. smooth strains, but not rough strains, are resistant to killing because they are protected from the MAC by long-chain LPS), while Gram-positive bacteria are not susceptible to MAC, due to complement evasion strategies. Enveloped viruses and parasites may also be susceptible to MAC, and those that are not have developed complement evasion strategies.

Opsonization for efficient pathogen phagocytosis and killing

There are many routes by which C3b sub-fragments and C4b deposited on target cells can lead to efficient phagocytosis and elimination. Complement activation on a pathogen or altered self surfaces leads to abundant C4b and/or C3b molecules that are converted to iC3b and C3d/dg by FI with the help of cofactors (Fig. 7C). For phagocytosis to occur, most of these fragments will be recognized by complement receptors CR1, CR3, and CR4 on phagocytic cells. These receptors each have a multitude of functions and ligands; this section summarizes how they participate specifically in phagocytosis for elimination of pathogens. CR1 (CD35) that is present on several immune cells, including mononuclear phagocytes and neutrophils, recognizes mainly C3b on pathogens,

although it can also recognize C4b and iC3b (with less affinity). CR3 (Mac-1, CD11b/CD18) and CR4 (p150,95, CD11c/CD18) are present on several types of immune cells, including mononuclear phagocytes and neutrophils. Both receptors recognize opsonizing iC3b on the pathogen surface and lead to destruction by phagocytosis.

It is important to note that CR3 and CR4 have a multitude of additional functions that will also contribute to pathogen killing. Aside from phagocytosis, CR3 participates in neutrophil activation, respiratory burst, degranulation, netosis, and regulating cytokine production (Bullard, 2018), while CR4 promotes cytokine production from monocytes, triggers neutrophil respiratory burst, and plays a role in monocyte and neutrophil adhesion (Georgakopoulos et al., 2008; Ren et al., 2004; Keizer et al., 1987; Stacker and Springer, 1991).

Initiating molecules of the CP and LP (C1q, MBL, and Ficolins) can bind directly to pathogen-associated molecular patterns (PAMPs) on certain pathogens and directly promote their phagocytosis. For example, (a) C1q can bind *Trypanosoma cruzi*, *Schistosoma mansoni*, *Listeria monocytogenes* (Alvarez-Dominguez et al., 1993; Rimoldi et al., 1989), and others; (b) MBL enhances phagocytosis of *Neisseria meningitidis* (Jack et al., 2005) and others; and (c) Ficolins promote phagocytosis of *E. coli*, *Salmonella typhimurium*, and others (Hajishengallis and Russell, 2015).

Pathogen complement evasion strategies that prevent killing

Although the complement system is a highly sophisticated innate defense mechanism that eliminates pathogens via direct killing and/or opsonophagocytosis, healthy individuals still succumb in infections, because many pathogens have evolved effective complement evasion strategies. Some of these include the secretion of convertase inhibitors, the expression of complement regulators that mimic the function of human regulatory proteins, capturing host regulators to protect themselves, preventing insertion of the MAC due to cell wall structure, capturing and inactivating initiating molecules of complement (e.g. immunoglobulins, C1q, etc.), and others. Some intracellular pathogens even use opsonization to their advantage for gaining entry into cells via complement receptor CR3, or bind directly to complement receptors CR3 and CR1. These concepts have been extensively reviewed elsewhere (Lambris et al., 2008; Hovingh et al., 2016; Ogembo et al., 2013).

Functions related to the generation of proinflammatory mediators

Small soluble cleavage fragments of some complement proteins can initiate inflammatory responses

When complement C3, C4 and C5 are cleaved during the course of complement activation, small fragments (C3a, C5a, C4a) are released into the blood or surrounding cellular microenvironment. Fragments C3a and C5a have specific receptors (C3aR, C5aR1, C5aR2) on a wide variety of cell types including neutrophils, eosinophils, mast cells, monocyte/macrophages, as well as endothelial cells, mast cells, smooth muscle cells, and others (Martin et al., 1997; Ohno et al., 2000). They can even be found intracellularly on T cells, with effects on T cell biology. C3a and C5a are also called anaphylatoxins due to their ability to induce smooth muscle contraction, increased vascular permeability, and basophil and mast cell degranulation. C4a, due to the lack of an identified receptor and very low anaphylatoxin activity (100–1000-fold less than C3a), may not be an actual biological anaphylatoxin (Hugli et al., 1983; Barnum, 2015; Klos et al., 2013). C3a and C5a are also chemotactic molecules that directly attract neutrophils, eosinophils, basophils, and monocytes to the sites where complement is activating.

C3a, once bound to C3aR (a G-coupled receptor) on myeloid receptors, participates in cellular activation, chemoattraction, degranulation and cytokine production [reviewed in Coulthard and Woodruff (2015)]. C3a-C3aR interaction has several proinflammatory properties overlapping with C5aR (below); however, C3a is much less potent than C5a in its functions and also can mediate anti-inflammatory functions in a cell-specific manner, likely dependent on the concentration of C3a (e.g. enhancement or inhibition of cytokine production) [Ember and Hugli, 1997; reviewed in Barnum and Schein (2018b) and Coulthard et al. (2018a)].

C5a carries out anaphylatoxin functions, as mentioned above and also is a very potent chemoattractant molecule (more potent than C3a), that, once bound to its primary specific receptor, C5aR1 (CD88; a G-coupled receptor), attracts all cells mentioned above, and tissue resident macrophages, including microglia. C5a-C5aR1 interaction controls effector functions of these cells, inducing, for example, degranulation and proinflammatory mediator release, and enhancing phagocytosis. C5a can also have opposing modulatory functions (pro-inflammatory or anti-inflammatory) on chemotaxis, degranulation, apoptosis, and cytokine production, depending on the extracellular concentrations of C5a and the cell type [reviewed in Coulthard et al. (2018b)]. This variability in C5a consequences makes it capable of either contributing to low grade inflammation needed for normal control of infection, healing, and homeostasis, or to severe inflammation, inducing even a cytokine storm. C5a can also bind to C5aR2 (C5L2; not coupled to G-proteins). Less is known about the consequences of the C5a-C5aR2 interaction. It may have both pro-inflammatory and anti-inflammatory consequences, and one possible function may be to serve as a modulator of C5aR1 signaling (Strainic et al., 2013; Arbore et al., 2016).

Functions related to housekeeping and homeostasis

The complement system plays essential roles in housekeeping functions including clearance or solubilization of immune complexes and clearance of dead and dying cells in a way that does not induce pathological inflammation. These two phenomena will be described below. Research in the complement system is also in the process of defining mechanisms by which both extracellular and intracellular complement pathways participate in cellular metabolism and homeostasis (i.e. regulation of autophagy, adipose tissue

metabolism, etc.), and this novel field has been reviewed elsewhere (Kolev and Kemper, 2017; King et al., 2019; Rahman et al., 2020).

Clearance of immune complexes

Antigen/antibody complexes in the blood activate the CP, because the antibody Fc regions are close enough together to bind C1q. Once the immune complexes are opsonized with C3b fragments, they are recognized by complement receptor CR1 on erythrocytes. These erythrocytes transport the opsonized immune complexes to the spleen or liver, where the immune complexes are taken up by resident tissue macrophages via CR3, CR4, or CR1. The erythrocytes then return to the circulation. Removal of immune complexes avoids immune complex-mediated inflammatory responses, including vasculitis due to deposition of excess immune complexes in the vasculature [reviewed in Walport and Lachmann (1988)].

Clearance of apoptotic cells

Recognition and removal of apoptotic and necrotic cells needs to occur efficiently and in a tightly controlled manner in order to avoid excessive inflammation and autoimmune responses. Apoptotic and necrotic cells are recognized by complement C1q, MBL, and Ficolins, via recognition of various ligands (e.g. C-reactive protein that binds to these cells, phosphatidylserine, and others), which triggers complement activation and deposition of opsonizing C3b. These opsonized cells are phagocytosed without pathological inflammation (Mevorach et al., 1998; Gershov et al., 2000). As discussed in previous sections, normal healthy cells are protected from complement activation by complement regulators. The reason that complement can activate on apoptotic cells is because membrane-bound regulators are partially downregulated (Elward et al., 2005) allowing limited complement activation, while CD59 (regulator of MAC) is still present; thus MAC is not formed. FH and C4BP also participate in regulating the process. This allows the opsonized apoptotic cells to be removed by phagocytosis, without inflammatory consequences. If dead and dying cells are not cleared (i.e. to deficiency in early CP components), there is an increase of dangerous autoantigens released from the cells and increased susceptibility to immune complex disease (e.g. SLE).

Another mechanism that contributes to elimination of apoptotic and necrotic cells involves binding of C1q and MBL to the dying cell, followed by the recognition of their collagenous tails by cC1qR (calreticulin) receptor on macrophages. cC1qR does not have a transmembrane domain and uses CD91 ($\alpha 2$ -macroglobulin) as an adaptor molecule. The apoptotic cell/C1q/cC1q/CD91 complex is taken up by micropinocytosis (Ogden et al., 2001).

Functions related to the adaptive humoral and cellular immune responses

B cell function

The best characterized complement-mediated function related to B cells is to opsonize antigen or immune complexes for uptake by complement receptor type 2 (CR2, CD21) expressed on B cells. B cells have on their surface a receptor (immunoglobulin) for recognizing a specific pathogen antigen, as well as a B cell co-receptor (CR2/CD19/CD81 complex). CR2 is a complement receptor present on B cells, follicular dendritic cells, and others, that recognizes sub-fragments of C3b [i.e. C3d/dg and iC3b (to a much lesser extent)]. Microbial antigens that are opsonized with C3d/dg can simultaneously engage both CR2 in the context of the B cell co-receptor and the microbe-specific immunoglobulin on the surface of a B cell, effectively activating the B cell. The presence of C3d/dg on the antigen and its interaction with CR2 lowers the amount of antigen needed to induce B cell responses by up to 10,000-fold (Carter et al., 1988; Dempsey et al., 1996). CR2 is also involved in B cell antigen presentation to T cells (Boackle et al., 1998) and has a role in the determination of B-cell tolerance toward self-antigens [reviewed in Boackle (2018)].

Interplay with T cells

Complement influences T cell immunity in many essential ways and unveiling the mechanisms involved is a hot topic that is ever-evolving in the field. There are several excellent reviews that address this topic in detail (Lo and Woodruff, 2020; West et al., 2018; Merle et al., 2015b; Hess and Kemper, 2016); herein, a few examples will be given to illustrate the variety and relevance of complement in T cell immunity.

The anaphylatoxins C3a and C5a, and their respective receptors (C3aR and C5aR), have roles in T cell function. C3a provides homeostatic signals to T cells and modulates metabolism, C5a is involved in polarization of T cell responses, modulation of T cell effector functions, and regulation of apoptotic cellular pathways. These effects are primarily thought to occur via C5a modulation of several different cytokines and interleukins. C3a, C5a, C3aR and C5aR have also been found intracellularly (Arbore et al., 2016). Intracellular C3a is generated by Cathepsin L-mediated cleavage of intracellular C3, and the source of intracellular C3 may come from the uptake of the hydrolyzed form of C3, C3(H₂O), from the blood by immune cells (Elvington et al., 2017). C3a in resting T cells is required for homeostatic CD4⁺ T cell survival. Intracellular C3a and C3b can transfer to the cell surface and engage C3aR and CD46, respectively, which is needed for interferon IFN γ secretion and induction of protective human T_H1 responses [reviewed in West et al. (2018)]. In the case of intracellular C5, the protease that cleaves it has not been identified. In activated T cells, intracellular C5aR1 signals have various functions in T cells, including inducing generation of reactive oxygen species and promoting NLRP3 inflammasome assembly, increasing T_H1 responses to infection (Arbore et al., 2016).

C1q also has several functions that influence T cells. One way is mediated by C1q interaction with dendritic cells via cC1qR receptor (calreticulin; receptor for the collagenous tails of C1q). Depending on what C1q is coupled to (e.g. antigen or apoptotic

self-cells), it will induce differential cytokine production by dendritic cells which will either promote T_H1 polarization or inhibit it, respectively [reviewed in Lo and Woodruff (2020)].

Functions related to complement system and coagulation system cross-talk

The complement system is not only a significant contributor to inflammation, but also to thrombosis. There are several points of intersection between the complement and coagulation systems that, when excessive, can lead to complement-mediated pro-thrombotic disorders, such as paroxysmal nocturnal hemoglobinuria, atypical hemolytic uremic syndrome, and thrombosis in infectious states, such as COVID-19. Some examples include: (a) C5a-mediated tissue factor (TF) expression on neutrophils (Johnstone, 2006) and endothelial cells, von Willebrand factor secretion from endothelial cells (Foreman et al., 1994), and upregulation of CR3 on neutrophils with resulting increase in platelet/neutrophil aggregates in blood (Blatt et al., 2016b; Hamad et al., 2015); (b) C5b-7-induced TF expression on monocytes (Langer et al., 2013) and C5b-8/C5b-9-mediated platelet activation (Wiedmer et al., 1986); (c) gC1qR (p33), a receptor for the globular heads of C1q, can also bind to high-molecular-weight kininogen (HK) and factor XII (FXII) on endothelial cells, leading to activation of the contact coagulation system (Ghebrehiwet et al., 2006); (d) C1-INH negatively regulates both factor XIa of the coagulation system and complement C1 (Meijers et al., 1988).

The crosstalk can also occur in the opposite direction. Certain coagulation enzymes, such as thrombin and factor Xa can directly activate components of the complement cascade. For example, C5 can be directly cleaved, leading to C5 convertase formation in the absence of C3 (Huber-Lang et al., 2006).

The complement system in disease

Overview

The essential and pleiotropic nature of complement functions and the relevance of the regulatory mechanisms involved, are clearly illustrated when the underlying pathophysiology of a wide variety of diseases is examined. Complement deficiencies account for ~5% of primary immunodeficiencies. This section will cover examples of: (a) diseases due to deficiencies in complement proteins; (b) diseases due to deficiencies in complement regulatory proteins; and (c) complement activation-mediated pathology, without defects in the complement system itself.

Deficiency in complement proteins

Deficiency in early CP complement components

Deficiency of early components of CP (C1q, C1r/s, C4, C2) predisposes to the autoimmune disease systemic lupus erythematosus (SLE) and immune complex disease, due to an increase in dangerous autoantigens and immune complexes that cannot be properly removed via the normal housekeeping functions of the CP (described in a previous section). Over 50% of individuals with deficiencies in C1q, C1r, C1s, and C4 develop SLE (Kaul et al., 2016). In addition, autoantibodies against C1q are observed in ~ a third of patients with SLE, which may block C1q function, mimicking C1q-deficiency (Leffler et al., 2014). SLE is one of most prevalent immune complex diseases that is 10× more common in females. Glomerulonephritis and arthritis are two of the most frequent symptoms and vasculitis is also found. Immune complexes trapped or formed in tissues (e.g. kidney and synovial tissue) lead to complement-mediated tissue injury to kidneys and joints (Ballanti et al., 2013).

Deficiencies in CP components also predispose to recurrent respiratory infections from encapsulated bacteria such as *S. pneumoniae*, *H. influenzae*, and *N. meningitidis* (Macedo and Isaac, 2016).

Deficiencies in LP proteins

Deficiencies in MBL (~5% of Caucasians) or Ficolins increase susceptibility to secondary infections and autoimmunity in infants and immunocompromised patients, while healthy individuals are usually asymptomatic due to intact CP and AP activity (Degen and Thiel, 2013). Deficiency in MASP-1 causes 3MC syndrome (Malpuech-Michels-Mingarelli-Carnevale syndrome), which is a rare disease characterized by developmental abnormalities and mental and growth retardation (Sirmaci et al., 2010). Some MASP-2-deficient individuals (~4% of Caucasians and up to 18% of some African populations) have increased risk of infection or autoimmune disease, but most are asymptomatic (Thiel et al., 2007 reviewed in Brodzski et al., 2020).

C3 deficiency

C3 is the most abundant protein in the complement system, with serum levels of approximately 1 g/L in both adults and newborns. Given all the roles that C3 cleavage fragments are needed for, including cytolysis, increasing vasopermeability, opsonization, clearance of immune complexes, facilitation of B cell proliferation and differentiation, and dendritic cell maturation, its deficiency leaves the individual severely immunocompromised. Individuals lacking C3 are highly susceptible to encapsulated bacteria (e.g. *S. pneumoniae*) and all pyogenic infections (recurrent, systemic), such as from *S. aureus*, *S. pyogenes*, and *N. gonorrhoeae*, and frequently suffer from immune complex-related disorders, such as glomerulonephritis and SLE. The rare deficiency is caused by mutations in the C3 gene, leading to absence or markedly reduced levels, or to dysfunction of the protein (Ghannam et al., 2008;

Figueroa and Densen, 1991; Macedo and Isaac, 2016; Okura et al., 2016; Grumach and Kirschfink, 2014; Pekkarinen et al., 2015; Reis et al., 2006).

Deficiencies in terminal complement components (C5, C6, C7, C8, C9) or FD or FB

C8 binds C5b67 and initiates C9 polymerization, leading to MAC formation. Genetic deficiency in C5, C6, C7, C8, C9 leads to increased susceptibility to invasive meningococcal infections, in particular with *Neisseria sp. (meningitidis and gonorrhoeae)*, resulting in dissemination of gonococcal infection, meningitis, and septic arthritis. Individuals with these deficiencies can lead a mostly normal life by receiving a tetravalent meningococcal vaccine (e.g. Menactra) as prophylaxis (Fijen et al., 1998). Similarly, FD deficiency leads to meningitis and gonococcal infections (Sprong et al., 2006). FB deficiency was thought to be non-existent and lethal until recently identified in an individual that presented recurrent bacterial infections including meningitis by *Neisseria*, pneumococcal peritonitis, and pneumococcal pneumonia (Slade et al., 2013).

Deficiency in complement regulatory proteins

A fine balance of positive and negative regulation of complement is essential in order to avoid disease.

Deficiency in C1-esterase inhibitor (C1-INH)

As explained in a previous section, C1-INH regulates C1, MBL, and Ficolins of the complement system, but also controls the contact activation system by inhibiting factor XIIa and plasma kallikrein, which are involved in the formation of bradykinin, a potent vasodilator molecule. C1-INH deficiency is rare and causes a disease known as hereditary angioedema or hereditary angioneurotic edema (HAE or HANE, respectively) that manifests as spontaneous episodes of skin, laryngeal and intestinal subcutaneous and submucosal edema. Although C1-INH leads to dysregulation of the CP and LP of complement, the edema is due to bradykinin production by the uncontrolled contact system [Nussberger et al., 1998; reviewed in López-Lera et al. (2019)]. In some textbooks the C2a fragment of C2 is still referred to as “C2 kinin” and implicated in the pathogenesis of HAE as well, but this is not the case, as the C2a fragment has been shown to not have kinin activity, and thus C2 kinin does not actually exist (Kaplan and Ghebrehiwet, 2005). HAE is not an allergic disease (attacks not mediated by histamine) and there is no itching associated to the swelling. The edema in the gastrointestinal tract may cause severe abdominal pain and vomiting and sometimes diarrhea. HAE episodes are infrequent in early childhood, but exacerbations occur during adolescence and continue throughout life. Because HAE patients still have an intact AP, patients are not unduly susceptible to infection. HANE is corrected by replacing C1-INH (FDA-approved, purified C1-INH: Berinert®, CINRYZE®, and HAEGARDA®, or recombinant C1-INH: RUCONEST®). This is an ideal alternative to using anabolic androgens (e.g. testosterone ethanate, danazol) for treatment, especially in women.

Properdin deficiency

Properdin is required for efficient function of the AP, by promoting AP activity through AP convertase stabilization and potentially initiating convertase formation. Deficiency of properdin is inherited as a recessive X-linked trait and leads to reduction in C3 cleavage and all down-stream effects. Patients are thus highly susceptible to *Neisseria* meningitis, otitis media, and pneumonia [reviewed in Chen et al. (2018) and Figueroa and Densen (1991)].

Factor I deficiency

One of the essential functions of FI is to control complement in the fluid phase and on cell surfaces by cleaving C3(H₂O) and C3b fragments into iC3(H₂O), iC3b and C3d/dg, with the help of cofactors. New convertases cannot be formed on these C3 fragments. In the absence of FI, the C3(H₂O) and C3b will not be cleaved by FI and new convertases will be readily formed, leading to complete consumption of C3 and FB (very low or undetectable levels in plasma). The essential function of FI becomes evident when considering that it is needed for cleaving the thousands of C3b molecules that are on surfaces where complement activates and amplifies successfully (such as pathogens). The abundant iC3b and C3d/dg molecules that are formed will serve as opsonic and immunostimulatory molecules to achieve adequate immune responses (Fig. 8C and 7C). Thus, the absence of FI leads to severe immunodeficiency, increasing susceptibility to pyogenic infections (e.g. otitis media, bronchitis, sinusitis, tonsillitis, etc.) [reviewed in Reis et al. (2006)]. Heterozygous individuals produce about half of the normal amounts and this is sufficient to prevent clinical symptoms (Barrett and Boyle, 1984). Clinical findings are similar to C3 deficiency and to agammaglobulinemia (i.e. no formation of C3d leads to no co-stimulation of B cell activation).

Defects in the function of Factor H and other regulators that lead to renal and ocular pathologies

FH is a critical negative regulator of both fluid phase and cell-bound complement activity, in order to protect our cells and tissues from complement-mediated attack. FH carries out its function via decay acceleration and by acting as a cofactor for FI (Fig. 7B and C). FH consists of 20 SCR domains, arranged like beads on a string, where the N-terminal domains 1–5 contain the functional site of the protein, while polyanion- and C3b/d-binding sites (for recognizing cell surfaces) are distributed throughout the protein. SCR domains 7 and 19–20 are considered particularly relevant for recognition of host cells for anchoring FH to the surface to carry out its protective functions [reviewed in Ferreira et al. (2010b) and Haque et al. (2020)]. Understanding the distribution of these sites allows for a better understanding of how diseases are associated to FH dysfunction, depending on whether FH is completely deficient, or if a particular domain of FH is defective. Thus, FH deficiency leads to the inability to accelerate the decay of AP

convertases and to act as a cofactor for FI in the fluid phase and on cell surfaces. Because FH is the main regulator of complement activity in the fluid phase of blood, FH deficiency leads to complete consumption of C3. This massive, chronic consumption of C3 (C3 synthesis is normal) leads to uncontrolled deposition of C3b, iC3b, and C3d/dg on cells, with damage particularly to the basement membrane of the kidneys that rely mainly of FH for protection, resulting in type II membranoproliferative glomerulonephritis (MPGN). Some individuals also have increased risk to infections.

On the other hand, when congenital mutations occur in the C-terminus of FH, FH can still regulate complement in the fluid phase of blood (the levels of C3 remain normal), but it cannot bind properly to host cell surfaces in order to regulate complement, resulting in cell damage. This results in the potential development of atypical hemolytic uremic syndrome (aHUS), a hematological disease that causes hemolysis, thrombi formation, renal failure and death. For aHUS to manifest, it usually requires a triggering event, including renal endothelial cell damage secondary to pregnancy/postpartum, infections, autoimmune disorders, or certain pharmacological treatments [reviewed in [Nester et al. \(2015\)](#)]. The current FDA-approved treatment for aHUS is C5-inhibition with anti-C5 monoclonal antibody Eculizumab or Ravulizumab.

aHUS can also be caused by mutations in other regions of FH, or in complement regulators FI, MCP/CD46, or by anti-FH autoantibodies, as well as gain-of-function mutations in C3 or FB [reviewed in [Nester et al. \(2015\)](#)]. Other renal pathologies caused by AP dysregulation include rare C3 glomerulopathies (C3G) and IgA Nephropathy (IgAN), the most frequent adult glomerulonephritis [reviewed in [López-Lera et al. \(2019\)](#)].

In the case of ocular pathology, when SCR domain 7 of FH or FHL-1 have a particular polymorphism, Y402H, individuals are significantly more likely to develop age-related macular degeneration (ARMD), the main cause of blindness in the elderly, due to deficient control of complement activation within the retina [reviewed in [López-Lera et al. \(2019\)](#)].

Deficiency in CD55 and CD59

CD55 and CD59 are glycosylphosphatidylinositol (GPI)-anchored membrane proteins. Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal hematopoietic stem cell disorder in which mutations in the PIG-A (phosphatidylinositol glycan class A) gene result in a deficiency of GPI anchor, and thus absence CD55 and CD59. The lack of complement control by these regulators on cells derived from the defective clone (red blood cells, platelets, etc.) results in intravascular and extra-vascular hemolysis and thrombi formation. PNH patients have dark early morning urine due to hemolysis and are diagnosed by a positive HAM test that consists of a serum lysis assay where PNH red blood cells readily lyse in the presence of acidified normal human serum, while normal cells do not. Flow cytometry using red blood cells from patients for detection of CD59/55 is now more common for diagnosis. Although bone marrow transplant is the only cure for PNH, patients can be treated for life with the FDA-approved anti-C5 monoclonal antibody Eculizumab or Ravulizumab ([Risitano et al., 2019](#); [Rondeau et al., 2019](#); [McKeage, 2019](#)).

Complement-mediated pathology where defects in complement proteins or regulators are not required

Although complement is known as an essential defense mechanism, complement activation on our own cells is possible and sometimes necessary, such as occurs during housekeeping functions and when local promotion of inflammation is needed (e.g. under limited/normal activation conditions this could lead to transient increase in reparative local inflammation or removal of damaged cells by phagocytosis) [[Camous et al., 2011](#); reviewed in [Blatt et al. \(2016a\)](#)]. However, excessive complement activation, as a consequence of certain diseases, will overwhelm complement regulatory mechanisms and lead to pathologic, excessive inflammation and complement-mediated tissue damage. Some examples are explained below.

Immune complex diseases

Immune complexes (ICs) are produced wherever there is an antibody response to a soluble antigen. IC disease is a state in which vascular injury occurs due to circulating antigen-antibody complexes, formed by exacerbated and/or chronic immune reactions or when normal levels of ICs cannot be removed efficiently. The normal process for IC elimination involves complement and Fc receptors. The excess ICs end up depositing in the basement membrane of small blood vessels, serving as a focal point for complement-mediated damage, and complement-mediated and Fc-mediated recruitment and activation of inflammatory cells. Certain pathological situations generate levels of ICs that overwhelm the normal elimination processes, even when complement proteins and regulators are “normal”. Common manifestations include glomerulonephritis, synovitis and dermal vasculitis. Examples of immune complex diseases are antibody-mediated glomerulonephritis, bacterial endocarditis, SLE (can also have complement-independent etiology), mixed essential cryoglobulinemia (various infectious, autoimmune or cancer-driven etiologies leading to hypergammaglobulinemia), rheumatic disease, and (HIV)-associated immune complex renal disease [reviewed in [Poppelaars and Thurman \(2020\)](#) and [Leffler et al. \(2014\)](#)].

Complement in inflammatory diseases

Complement plays a role in the pathology of most inflammatory diseases including, but not limited to, ischemia/reperfusion, asthma, arthritis, cardiovascular diseases, acute and chronic transplant rejection, skin diseases, infectious diseases that lead to severe systemic and/or local inflammation (e.g. sepsis, viral infections such as that by COVID-19, etc.), and chronic inflammation in cancer, etc., and have been reviewed extensively by others ([López-Lera et al., 2019](#); [Lappegård et al., 2014](#); [Lo and Woodruff, 2020](#); [Roumenina et al., 2019](#); [Lo et al., 2020](#)). For example, in ischemia-reperfusion injury, such as that which can occur during transplantation reperfusion or traumatic injury, systemic inflammation and can result in multi organ failure from complement

activation. This is due to hypoxia-induced alteration of the cell surfaces with exposure of neoantigens that now can be activators of the AP or be recognized by natural antibodies to trigger the CP, triggering sterile inflammation. In the case of skin diseases, complement plays a role in the pathogenesis of pemphigus and bullous pemphigoid (BP) due to the presence of autoantibodies against skin antigens.

Complement in neuroinflammation/neurodegenerative diseases

Local synthesis of complement components by astrocytes, microglia and neurons, and oligodendrites in the brain (e.g. C1, C2, C3, C4, C5, C6, C7, C8, C9, FB) allows complement to play important roles in normal function and homeostasis in the brain, such as removal of apoptotic cells and cellular debris, developmental functions, neurogenesis, and synaptic pruning [reviewed in [Tenner et al. \(2018\)](#), [Hammad et al. \(2018\)](#), and [Lo and Woodruff \(2020\)](#)]. In the context of disease, when complement-dependent synapse elimination is aberrant, it may contribute to neuropsychiatric and neurodevelopmental disorders. Expression of complement components increases in the brain during aging and especially in Alzheimer's disease. Also, excessive complement-mediated synapse pruning occurs in aging, Alzheimer's disease and other disorders such as Parkinson's disease, multiple sclerosis, and Huntington's disease that correlate with cognitive or behavior impairments [reviewed in [Morgan \(2015\)](#) and [Tenner et al. \(2018\)](#)]. In addition, complement is involved in traumatic brain injury pathology, where due to loss of blood/brain barrier integrity, excessive amounts of complement from leukocytes and blood contribute to massive inflammation [reviewed in [Hammad et al. \(2018\)](#)].

Complement in cancer

Complement has a several functions in the context of cancer including directly promoting proliferation and metastasis, stimulating angiogenesis, and regulating or generating an immunosuppressive microenvironment. The tumor microenvironment highly influences the growth and spread of tumors, thus impacting the clinical outcome. In the tumor microenvironment, complement may either act to kill antibody-coated tumor cells, or on the contrary, support local chronic inflammation and/or hamper anti-tumor T cell responses, favoring tumor progression. For example, C5a stimulates myeloid-derived suppressor cells (MDSC), which dampen the immune response, suppressing cytotoxic T cells, and stimulate T regulatory cells. C3a, C5a, and C5b-9 promote angiogenesis, helping in tumor nutrient support and dissemination [reviewed in [Roumenina et al. \(2019\)](#)]. Normal mature neutrophils also acquire a suppressor phenotype within the tumor microenvironment that requires a number of neutrophil effector functions, including complement activation ([Singel et al., 2019](#)). The role of complement is highly variable depending on the type of cancer; thus, modulation of the complement system as potential cancer therapy will likely need to be used within the context of personalized medicine.

Autoimmune hemolytic anemia

Autoimmune hemolytic anemia is an uncommon type II autoimmune disease that results in complement- and Fc receptor-mediated hemolysis after recognition of the autoantibodies on the surface of red blood cells. In approximately half of cases, the cause of autoimmune hemolytic anemia is idiopathic or primary; however, it can also be associated with other disorders (secondary) such as autoimmune disease, chronic lymphocytic leukemia, and other blood cancers, hepatitis, HIV, etc. It can also occur following the use of certain drugs (such as penicillin) or after a bone marrow stem cell transplant [reviewed in [Braunstein \(2020\)](#)].

General overview of therapeutic targets

As explained in the previous section, (a) the complement system must be tightly controlled otherwise it leads to unwanted complement-mediated damage of host cells, causing several possible diseases, and (b) complement activity plays a role in disease pathogenesis, even when regulation is intact. Anti-complement therapeutics targeting a wide variety of stages of the complement system is proving effective in many of these disease scenarios and are prevalent in clinical trials, which are quickly evolving and extensively reviewed elsewhere [reviewed in [Zipfel et al. \(2019\)](#), [Ricklin et al. \(2018\)](#), [Tomlinson and Thurman \(2018\)](#), and [Zelev et al. \(2019\)](#)]. So far, the only FDA approved drugs with complement connectivity, used in controlling complement-mediated pathology, include: (a) the anti-C5 antibodies, Eculizumab and Ravulizumab, for the treatment of PNH and aHUS, and (b) purified or recombinant replacement therapy of C1-INH (i.e. Berinert®, CINRYZE®, and HAEGARDA®: Human derived C1-INH, and RUCONEST®: recombinant C1-INH) in hereditary angioedema (HAE) where C1-INH deficiency causes dysregulation of the complement and kinin systems. Individuals receiving anti-C5 therapy need to be concomitantly vaccinated with the meningococcal vaccine as well as vaccines to prevent *Streptococcus pneumoniae* and *Haemophilus influenza* type b.

Basic laboratory assays for assessing overall complement function and disease diagnostics

Common clinical tests for assessing complement consist of measuring overall CP and AP activity, and C3 and C4 levels by hemolytic assays [Morgan \(2010\)](#) or ELISA-based assays ([Seelen et al., 2005](#)). Additional immunometric tests exist to measure levels and functions of all complement components, as well as to identify autoantibodies against certain components (e.g. C1q or FH), but not

all tests are available in all clinical laboratories. Depending on the suspected disease and following identification of quantitative functional defects, an underlying genetic cause can be confirmed by genetic screening. Complement tests and the criteria used for selecting them, as well as their limitations, have been thoroughly reviewed by the European Society for Immunodeficiencies and European Reference Network on Rare Primary Immunodeficiency, Autoinflammatory and Autoimmune Diseases (Brodzski et al., 2020). Often, complement analysis in clinical practice is restricted to cases in which complement deficiency is suspected in patients due to increased susceptibility to severe infections. However, complement defects may also present as autoimmune diseases (e.g. SLE), ARMD, renal disorders (e.g. aHUS and other C3 glomerulonephropathies) and angioedema. Early diagnosis of complement deficiency decreases the risk of severe infections during childhood and may avoid irreversible tissue damage when prophylactic treatment (i.e. vaccination and anti-complement therapeutics) is administered.

Basis of hemolytic assays that measure general CP and AP activity

Although ELISA kit assays are available commercially for obtaining CH_{50} and AP_{50} values, herein, the traditional hemolytic assays will be described as a way to review how the CP and AP pathways function.

CH_{50} hemolytic assay

The CH_{50} assay consists of CP-mediated hemolysis of IgG or IgM-coated sheep erythrocytes. The anti-sheep antibodies used are also referred to as hemolysin. Sheep erythrocytes are used because of the high levels of the polyanion, sialic acid, on the cell surface, which allows them to be very effectively protected by FH. Thus, these erythrocytes are resistant to the AP. This assay also requires Ca^{++} for stability of C1 and Mg^{++} for stability of the convertases. Patient serum is incubated with the antibody-coated sheep erythrocytes and hemolysis is measured. The assay is performed in parallel with normal human reference serum. The result is expressed as the reciprocal of the amount of patient serum necessary to lyse 50% of the erythrocytes (due to MAC formation). Thus, the lower the CH_{50} value, the less active complement is in the serum (compared to values from the normal human serum standards). The reduced activity may be due to primary deficiencies in C1(q, r, s), C2, C3, C4, or C5b-9, or to complement consumption due to defective or absent C1-INH, C4BP, FI, and FH, or certain chronic infectious or inflammatory diseases.

AP_{50} hemolytic assay

The AP_{50} assay relies on AP-mediated hemolysis of erythrocytes lacking surface expression of polyanions (e.g. rabbit, guinea pig, chicken). Without polyanions, these erythrocytes are effectively lysed by the AP because they will not be protected by FH. This assay requires Mg^{++} for stability of the convertases. Because these erythrocytes are not coated with antibodies and Ca^{++} is absent, the CP does not readily activate, thus AP function is adequately assessed. Patient serum is incubated with erythrocytes and hemolysis is measured. The assay is performed in parallel with normal human reference serum. The result is expressed as the reciprocal of the amount of patient serum necessary to lyse 50% of the erythrocytes (due to MAC formation). Thus, the lower the AP_{50} value, the less active complement is in the serum (compared to values from normal human serum standards). The reduced activity may be due to primary deficiencies in C3, FB, FD, C5b-9, properdin, or complement consumption due to defective or absent FI and FH.

Conclusion

The complement system is multifaceted and comprises a versatile set of molecules that participate in innate and adaptive immunity. The main points discussed in this article emphasize the extraordinary characteristics of complement (no longer considered just a set of circulating molecules restricted to innate immunity), including participating in circulating and local tissue defense and homeostatic processes. These processes include fighting off infections by direct killing and removal by phagocytosis, modulating adaptive cellular immune responses, removing dead and dying cells and immune complexes from circulation, among others. Given the essential functions of complement, it needs to be tightly regulated in order to not cause unwanted damage to self. When integrity of either a complement cascade protein or of a complement regulator is compromised (via primary or secondary deficiencies or loss or gain-of function mutations), a wide range of disease scenarios ensue, including severe infections, autoimmune disorders, eye and/or renal disorders, or angioedema, etc. Moreover, even when all complement cascade proteins and regulators are functionally intact, complement can contribute to disease pathogenesis, for example, via fluctuating concentrations of complement cascade proteins and/or complement regulatory proteins, locally and/or systemically, and/or modulation in expression, due to consumption during infections or acute and chronic inflammatory diseases. Moreover, in many disease scenarios, such as immune complex disease, ischemia reperfusion injury, and others, the normal housekeeping functions of complement as well as the ability to regulate itself are overwhelmed, contributing to pathology. Currently, there are few FDA-approved therapeutics to target complement, but there are many promising ongoing clinical trials aimed at assessing the efficacy of inhibiting complement at multiple stages of the cascade. The continued study of molecular mechanisms involved in complement-mediated disease pathology will continue to be essential. Finally, a large number of investigators groups have made essential contributions over the past century, only a portion of which have been cited here due to space constraints. Excellent reviews have been cited in an attempt to compensate for omissions.

Glossary

Cytokine storm and COVID-19 Cytokine storm is a hyperinflammatory state due to overactivity of major pro-inflammatory cytokines like IL-1, IL-6, and TNF. It is a major obstacle for the treatment of severe COVID-19. The latest analyzes of the SARS-CoV-2 infection show IL-6 as a potential biomarker for the severity of the disease. Anti-IL-6R (tocilizumab) and remdesivir antiviral therapies show promise in the treatment of severe disease. Prevention measures are in place with many auspicious novel vaccines.

IL-6 IL-6 family of cytokines is structurally distinct from IL-1/IL-18 or TNF families. They are characterized by four α -helical bundle structure that signals via the JAK-STAT pathway. IL-6 has a major role in innate and adaptive immunity. IL-6 classic signaling is implicated in acute-phase responses, whereas IL-6 *trans*-signaling (and *trans*-presentation/cluster-signaling) characteristically initiates pro-inflammatory pathways with a major impact on adaptive immunity, including plasma cell development and antibody production, and T-cell helper 17 response.

Interferons Antiviral cytokines or interferons are classified into three types. Type I interferons like IFN- α , β are early molecular effectors capable of inducing an antiviral state in cells. Almost all nucleated cells can produce IFN- α . Its predominant source is plasmacytoid dendritic cells (pDCs). IFN-type I and III (IFN- λ) stimulate both innate and adaptive immune responses. Type I IFNs can positively influence both cellular and humoral adaptive immunity. Type II interferon (IFN- γ) has a weak antiviral ability, but its major role is in regulating adaptive immunity, particularly in Th1 responses.

The IL-1 family Members of the IL-1 family of cytokines are similar in structure and function. Most receptors of this family have one chain (IL-1RAcP) in common in their heterodimeric receptors (IL-1R, IL-33R, and IL-36R). The functions include agonistic (pro-inflammatory) and antagonistic (anti-inflammatory) activities. There are seven agonists: IL-1 α , β , IL-18, IL-33, and IL-36 α , β , γ , and four antagonists: IL-1Ra, IL-36Ra, IL-37, and IL-38. Additional antagonists are IL-18BP and several soluble receptors (ST2, IL-1RAcP, IL-1R2-decoy). With these activities, the IL-1 family of cytokines can signal damage of tissue integrity, distress, and danger to the organism, ultimately alarming innate and adaptive immunity to fight pathogens.

TNF and LT TNF and LT are trimeric proteins belonging to a structurally related TNF superfamily of cytokines. They are pleiotropic cytokines capable of signaling an array of pro- and anti-inflammatory activities. TNF- α has soluble (sTNF) and membrane (mTNF) forms. Both forms can bind to two TNF receptors (TNF-R1 and TNF-R2), but mTNF can alter the structure of the TNF-R2 such that it binds to sTNF with a lower affinity. Thus, sTNF primarily binds to TNF-R1 and plays an important role in the inflammatory immune response, whereas mTNF- α interacts preferentially with TNF-R2 and promotes cellular proliferation and survival and some other biological effects.

Abbreviations

ADAM	A disintegrin and metalloproteinase
APC	Antigen-presenting cell
CTL	Cytotoxic T lymphocyte
DCs	Dendritic cells
FDA	Food and Drug Administration of USA
FDC	Follicular dendritic cells
GALT	Gut-associated lymphoid tissue
IBD	Inflammatory bowel disease
IDO	Indoleamine-pyrrole 2,3-dioxygenase
IFN	Interferon
IL	Interleukin
IL-1R1	IL-1 receptor chain 1
IL-1RAcP	IL-1 receptor accessory protein
ILCs	Innate lymphoid cells
iNOS	Inducible nitric oxide synthase
IRAK4	Interleukin-1 receptor-associated kinase 4
LT	Lymphotoxin
LT β R	Transmembrane lymphotoxin receptor
MHC I	MHC class I molecule
MHC II	MHC class II molecule
MHC	Major histocompatibility complex
MMP	Matrix metalloproteinase
MS	Multiple sclerosis
MyD88	Myeloid differentiation primary response protein 88
RA	Rheumatoid arthritis
SOCS1	Suppressors of cytokine signaling
STAT	Signal transducers and activators of transcription
TACE	TNF- α converting enzyme
Th	T helper cell
Th1	Th type 1 response
TIR	<i>Toll</i> /IL-1 resistance domain
TIRAP	TIR domain-containing adaptor protein
TLR	<i>Toll</i> -like receptor
TNF	Tumor necrosis factor
TNF-R	Tumor necrosis factor receptor
TOLLIP	<i>Toll</i> interacting protein
TRAF	TNF receptor-associated factor

Introduction

Cytokines are small proteins with a major role in inflammation and cell survival. Cytokines can be classified into several structural classes. We recognize the (1) helical cytokines (Nicola and Hilton, 1998), (2) the trimeric tumor necrosis factor (TNF) family (Idriss and Naismith, 2000), (3) the cysteine knot growth factors (Sun and Davies, 1995), and (4) the β -trefoil growth factors (Murzin et al., 1992). Cytokines can also be classified according to the type of receptor that they engage (Wang et al., 2009), and that has

been mostly used in chemokine descriptions. The cytokine receptors can be grouped into six major families based on shared structural features: (1) class I cytokine receptors, (2) class II cytokine receptors, (3) TNF receptors, (4) IL-1 receptors, (5) tyrosine kinase receptors, and (6) chemokine receptors (Fitzgerald et al., 2001; Thomson and Lotze, 2003).

Innate immunity cytokines have agonistic, antagonistic, and receptor antagonistic actions that also include soluble receptors and reverse signaling. They are essential regulators of tissue homeostasis (including wound healing). By provoking inflammation and distress in the body, some of them can alarm innate and adaptive immune systems to make a proper type of response to pathogenic infections. They are helped in these matters with many factors, including other cytokines, because most have multiple, sometimes overlapping functions.

IL-1, TNF, and interferons (IFNs) are important mediators in immunity. They were among the first ones identified. They differ in basic structure, but they are similar in functioning as a homeostatic mechanism to maintain integrity of an organism. Many shared functions include pro-inflammatory, anti-inflammatory and immunoregulatory activities.

The IL-1 family

IL-1 is a pleiotropic cytokine with pro-inflammatory, immunoregulatory, and hematopoietic effects. It can cause an increase in body temperature (Evans et al., 2015), bone resorption, muscle proteolysis, cachexia (indirectly via TNF), an increase in circulating acute-phase proteins such as C-reactive protein (CRP), and a decrease of iron and zinc plasma concentrations (Dinarello, 2009; Garlanda et al., 2013).

The IL-1 can be secreted by various stimuli. Pattern recognition receptors, including TLRs and their counterparts in inflammasomes, are the critical mediators in sending the alarm to activate defensive actions of innate and adaptive immune responses. Thus, pattern recognition, senescence, dysbiosis, necroptosis, tissue damage, and coagulation of blood are provoking stimuli that, with increasing strength, influence and amplify local innate and, in turn, adaptive immune responses, all of which could lead to a systemic inflammation with grave and sometimes fatal outcomes. The latter is called a *cytokine storm*, implicated in patients with severe COVID-19 disease. It is characterized by an acute increase in circulating levels of various pro-inflammatory cytokines, including IL-1 β , IFN- γ , TNF, IL-6, IL-10, and IL-18 (Ragab et al., 2020; Shimizu, 2019).

Target tissues for IL-1 are cells of the hematopoietic (lymphoid and myeloid) origin that subsequently regulate innate and adaptive immune responses by various cytokines, including IFN- γ and IL-17. The endothelial lining of blood vessels secretes chemokines and expresses adhesion molecules that lead to leukocyte recruitment to the pathological event site. The brain is affected and sets in motion effects like fever and hormone production (via hypophysis-pituitary axis, steroids) as a reaction to stress. These processes tend to help heal an organism when wounded, infected, or otherwise compromised by necrotic cell death in tissues. The central function of IL-1 in the connective tissue in wound healing, probably due to the angiogenic effect (Dinarello, 2011).

IL-1 α is a dual function cytokine similar to IL-33 and IL-37 (Li et al., 2019). It signals via surface membrane receptors, but it also translocates to the nucleus. If it is released from chromatin during necrosis or necroptosis (Werman et al., 2004), it could promote inflammation (and is the leading cause for sterile inflammation) (Cohen et al., 2010). However, if it stays bound to the chromatin (for unknown reason), as in the apoptotic cell death, then it would not cause inflammation (Cohen et al., 2010). Secretion of IL-1 α requires cleavage of the precursor pro-IL-1 α by the caspase-1 and calpain enzymes.

Thus, necrotic death, exemplified by the IL-1 precursor release, is a signal of distress for the innate and adaptive immune systems, as most necrosis is either caused by or present during infection by pathogens or parasites. On the other hand, apoptotic death is physiologic during embryonal development, tissue regeneration, and maintenance, and, if sterile, will not alarm the immune system, thereby avoiding the generation of autoreactivity and possibly autoimmune disease (Chen et al., 2007).

During T-cell activation, IL-1 promotes the development of the Th17 phenotype of helper T cells, accompanied by IL-21, IL-23, and polarizing (required) cytokines IL-6 and TGF- β , whereas IFN- γ , IL-2, IL-4, IL-12, and IL-27 block Th17 development.

The gene coding for human IL-1 α is IL1A, and the one encoding IL-1 β is the IL1B gene. They are on the chromosome 2q12–21. Other group members are also encoded in this segment of the chromosome and form the IL1 gene cluster. The IL-1 receptor antagonist (IL-1Ra) is encoded by a gene in the same *locus*, called IL1RN (Fig. 1).

The IL1 gene cluster includes nine genes encoding IL-1-alike cytokines on human chromosome 2q14.1 (at 112–113 Mb). Six of these genes are located in-between IL1A/IL1B on the one side and IL1RN gene on the other in the following order (in the direction from centromere to telomere): IL37 (alias: IL1F7), IL36G (alias: IL1F9), IL36A (alias: IL1F6), IL36B (alias: IL1F8), IL36RN (alias: IL1F5) and IL38 (alias: IL1F10).

Interleukin-1 receptor 1 chain (IL-1R1) is also called “antigen CD121a”. Its gene is named IL1R1. It is located on chromosome 2q12 (at 102 Mb), 10 Mb centromeric to the IL-1 gene cluster, close to the receptor of the IL18R gene. The gene for the accessory chain (IL-1RAcP; IL-1R3) of the IL-1R1 (and IL-1R2) is located on chromosome 3q28 (at 190 Mb) and is named IL1RAP (alias: IL1R3). Interleukin-1 decoy receptor chain (IL-1R2) is also called “antigen CD121b.”

In Fig. 2, IL-1 functions and its family members are illustrated. The IL-1, IL-12, IL-23, IL-25, IL-33, and TSLP affect innate cells *innate-like cell type 1* (ILC1), ILC2, ILC3, and natural killer (NK) cells each in its specific way (Garlanda et al., 2013).

Fig. 1 Agonists and antagonists in the IL-1 family. IL-1α, IL-1β, IL-18, IL-33 and IL-36 cytokines are agonists. Receptor antagonists (IL-1Ra, IL-36Ra, IL-37, and IL-38), soluble receptors' extracellular domains (sIL-1R2, sST2, and sIL-1RAcP), and IL-18 binding protein (BP) can downregulate their signal transduction.

Fig. 2 The IL-1 family of cytokines (IL-1, IL-18 and IL-33) actions: effects on innate and adaptive immune responses.

Innate lymphoid cells

Innate lymphoid cells are non-lymphoid-tissue-resident immune cells that lack antigen receptors or NK receptors, as has been reviewed (Fan and Rudensky, 2016; Vivier et al., 2018). ILCs are divided into five groups based on cytokines produced and transcription regulators involved in their generation and function: natural killer (NK) cells, ILC1, ILC2, ILC3 (which include

lymphoid tissue inducer, LT α cells), and ILCreg (Mortha and Burrows, 2018; Schenkel and Masopust, 2014; Godfrey et al., 2015; Spits et al., 2013; McKenzie et al., 2014; Klose and Artis, 2016). ILCs are derived from early innate lymphoid precursors (EILP), which can differentiate into common helper innate lymphoid precursors (CHILP) (Mortha and Burrows, 2018).

The ILCs resemble CD4 helper or CD8 cytotoxic T cell responses of adaptive immunity. The ILC1 type produces IFN- γ and has T-bet transcription factor like Th1 cells, whereas ILC2 produces IL-5, IL-13 and shares GATA-3 transcription factor expression with the Th2 type. The ILC3 group corresponds to the Th17 type as they express the ROR γ t transcription factor, and they can be further subdivided into CCR6 positive and CCR6 negative cells. Regulatory ILCreg cells express Id3 transcription factor, produce IL-10 and can suppress activation of ILC1 and ILC3 (Wang et al., 2017). This is similar to Tr1 or Tregs that can inhibit adaptive immune responses of Th1, Th2, and Th17 types. Then, innate immunity's conventional NK cells derive from EILPs and express transcription factors T-bet and Eomes that lead to a phenotype similar to CD8 cytotoxic T cells, as they both have cytotoxicity, produce and secrete IFN- γ , TNF, GM-CSF, and other similar proteins (reviewed in Mortha and Burrows, 2018; Klose and Artis, 2016; Vivier et al., 2018).

The plasticity of the development of ILCs is uncovered by finding that ILC2 and ILC3 can trans-differentiate into other ILC types. So, we have ex-ILC2 cells that produce IFN- γ and function as ILC1. Similarly, we have ex-ILC2 cells that produce IL-17A resembling the ILC3 group. Lastly, there is an ex-ROR γ t/ILC3/ILC1 group expressing T-bet nuclear factor, secreting IFN- γ and TNF cytokines, and producing granzyme, perforin, and natural cytotoxicity receptors similar to ILC1 and NK cells (Mortha and Burrows, 2018).

ILC2 and ILC3 integrate multiple signals consisting of predominantly soluble factors in exerting their actions. In detail, ILC2 cells receive activation from signals via IL-33 and TSLP from epithelial cells and myeloid cells, and IL-25 from tuft cells. Furthermore, IL-1 α and IL-1 β , derived from myeloid and epithelial cells together with IL-23 can activate ILC3.

While circulating adaptive lymphocytes (B and T cells) and conventional NK replenish their numbers from hematogenous sources, the resident ILCs populate their niches early in ontogeny and remain in their environment throughout life. Their renewal depends on the support of local tissue-resident progenitor cells (Bando et al., 2015). The markers on ILC include integrin α 4 β 7 (that binds to MadCAM-1, which is expressed on high endothelial venules of MALT like Peyer's patches) and the chemokine receptor CXCR6 that guides them to the intestine (Klose et al., 2014; Satoh-Takayama et al., 2014). Additional chemokines involved in intestinal residence are CCR9 receptors and CCR6 that can guide ILCs to mesenteric lymph nodes.

In concert with other factors, ILC1 can be stimulated by IL-18 to secrete IFN- γ and TNF after activation by myeloid-cell-derived IL-12. IL-1 can stimulate ILC3s to produce IL-17, IL-22, and GM-CSF. IL-33 can similarly induce ILC2 to secrete IL-5, IL-9, and IL-13. Furthermore, IL-1, IL-18 and IL-33 affect adaptive immune cells Th1, Th2, Th17, T γ δ 17 and CD8 T cells to secrete IL-4, IL-5, IL-15, IFN- γ , G-CSF and chemokine CXCL8 (IL-8). These cytokines influence macrophages (M1 and M2), neutrophils, mast cells, and other granulocytes (eosinophils and basophils) to fight against viruses, tumors, extracellular parasites, or extracellular bacteria. In addition, these actions may provoke allergic reactions or promote tumor growth, too (Fig. 2).

IL-1 with its cytokine family members like IL-18, IL-33, IL-36, IL-37, and IL-38 affect almost all cells and organs in the body.

Medical aspects

IL-1 is the major pathogenic mediator of autoinflammatory, autoimmune, infectious, and degenerative diseases. IL-1 cytokine and its receptor are involved in the etiology of various acute and chronic inflammatory diseases, including *Alzheimer's disease*, *atherosclerosis*, *endometriosis*, *kidney diseases*, *migraine*, *rheumatoid arthritis*, *septic shock*, and in the tumors like *bladder*, *gastric*, and *liver cancer* (Dinarello, 2009; Gabay et al., 2010; Sims and Smith, 2010). For example, IL-1 β , TNF, and IFN- γ stimulate gamma-secretase-associated cleavage of *amyloid precursor protein* (APP) via JNK-dependent MAPK, which may be the reason for increased production and accumulation of amyloid in *Alzheimer's disease* (Alasmari et al., 2018).

Because IL-1 is a key mediator of inflammation, for clinical purposes, there are attempts to inhibit the action of IL-1, particularly in *autoimmunity*, *osteoarthritis* (Jotanovic et al., 2012), and other inflammation-related diseases, some using the addition of anti-TNF treatment (Dinarello, 2011).

Tumor necrosis factor (TNF) and lymphotoxin (LT)

Historical aspect

Tumor necrosis factor (TNF) is a pleiotropic cytokine involved in immunologic processes of infection resistance, autoimmunity, allergic disease, and anti-tumor activity (Ruddle, 2014; Old, 1985), originally discovered in 1968, under the name lymphotoxin (LT), as a factor that promotes the killing of mouse fibrosarcoma (L-929) tumor cells (Kolb and Granger, 1968; Ruddle and Waksman, 1968). Then, in 1975, a factor named "tumor-necrotizing factor" TNF was discovered in experiments when serum from bacillus *Calmette-Guérin* (BCG)-infected mice treated with lipopolysaccharide (LPS) could cause hemorrhagic necrosis in tumors (Carswell et al., 1975). It was subsequently shown that TNF increase could lead to endotoxic shock accompanying malaria (Clark et al., 1981). When the cDNAs were cloned for TNF (Pennica et al., 1984) and LT (Gray et al., 1984), their sequence predictions reveal to be similar as well as their gene organization (Nedwin et al., 1985). Furthermore, functionally, they were homologous, too, as LT could displace TNF from binding to its receptor on target cells' cell surface. These discoveries led to the renaming of TNF as TNF- α and LT (also called LT- α) as TNF- β .

The story continues when another factor called cachectin (which induces cachexia, exhaustive loss of body weight) was cloned and discovered to be actually TNF (Beutler et al., 1985). TNF was discovered to be the key mediator in lethal septic shock, which could be successfully prevented by mAbs against it (Tracey et al., 1986; Tracey et al., 1987).

In humans, both TNF- α and TNF- β bind to two types of receptors (Hohmann et al., 1990) of apparent molecular masses of 55/60 kDa and 75/80 kDa that were identified by monoclonal antibodies (Brockhaus et al., 1990). The receptors were subsequently molecularly cloned and denoted TNF-R1 (Loetscher et al., 1990; Schall et al., 1990) and TNF-R2 (Smith et al., 1990; Dembic et al., 1990), respectively.

Finally, in 1993, a novel LT/TNF-like cytokine was discovered and was named LT- β . It could make heterotrimers with LT- α resulting in functionally important complex LT- $\alpha_1\beta_2$ for gut physiology (Browning et al., 1993). This event encouraged the reversal of the name TNF- β back into LT- α .

TNF- α and LT- α (TNF- β)

TNF- α and TNF- β (LT- α) share 30% similarity at the amino acid level. They belong to the superfamily of tumor necrosis factor (TNFSE, *tumor necrosis factor superfamily*), which has over 20 members and includes molecules such as FasL and CD40L (Smith et al., 1994; Locksley et al., 2001). The superfamily members are structurally glycoproteins with the transmembrane regions.

Human TNF- α can be expressed as a 26-kDa transmembrane-bound homotrimer (mTNF- α) (Kriegler et al., 1988) or as a soluble 17-kDa form (sTNF- α), which is produced by cleavage of the mTNF- α by ADAM17 metalloproteinase (Black et al., 1997).

The TNF- α and LT- α (TNF- β) genes, named TNFA and TNFB, respectively, are located within the MHC (HLA) locus on human chromosome 6.

Although TNF- α expression is ubiquitous, it is typically produced by activated macrophages, lymphocytes, and other cells. TNF- β (LT- α) is mainly produced by B-, T-, NK cells, and ILCs.

TNF is involved, together with IL-1, in the development of the Th17 response.

There are two receptors that TNF can bind: type 1 TNF receptor or TNF-R1 (CD120a), and TNF receptor type 2 or TNF-R2 (CD120b). TNF-R1 has MW of 55/60-kDa, and TNF-R2 has 75/80-kDa, and both are expressed as homotrimers in the cell membrane. The molecular cloning of receptors revealed that they belong to a large TNF/TNF-R-related superfamily (Loetscher et al., 1990; Schall et al., 1990; Smith et al., 1990, 1994; Dembic et al., 1990; Wallach et al., 1999; Locksley et al., 2001). TNF-R1 structure includes the death domain, which is not present in the TNF-R2. The TNF-R2 is mainly found on immunocytes (monocytes/macrophages, dendritic cells, B and T cells), endothelial cells, fibroblasts, oligodendrocytes, cardiomyocytes, keratinocytes, and some particular subsets of neurons (Medler and Wajant, 2019). TNF-R1 can be fully activated by both the membrane-bound and soluble trimeric forms of TNF. However, it seems that TNF binding to TNF-R1 is irreversible, whereas binding to TNF-R2 is reversible (Szondy and Pallai, 2017). The interaction between mTNF- α and TNF-R2 induces bi-directional (forward and reverse) signaling in both mTNF- α - and TNF-R2-expressing cells. Increasing evidence shows that the forward and reverse signaling mediated by mTNF- α and TNF-R2 might play a significant role in the tumor microenvironment (Szondy and Pallai, 2017).

A simplified version of TNF signaling is depicted in Fig. 3. It gives the basic principles of signaling through TNF-R1 and TNF-R2. The pathways are deposited and curated on the web at the WikiPathways database (ReactomeTeam et al., 2021).

Two TNF receptors (TNF-R1 and TNF-R2) have different intracellular domains and have variable outcomes (Dembic et al., 1990). Also, sTNF and mTNF differ in signaling, with mTNF being able to signal in a reverse direction. In short, TNF-R1, having the death domain, can promote cell death and pro-inflammatory actions, whereas TNF-R2 can collaborate with TNF-R1 signaling promoting cell survival (protection) and anti-inflammatory activities (Fig. 3). It seems that cell survival, proliferation, and death are a matter of quantitative balance between TNF-R1 and TNF-R2 and the key components of their respective signaling complexes (Gough and Myles, 2020).

Concerning the membrane-bound form of TNF (mTNF) - receptor interaction, mTNF was found to bind TNF-R2 (Grell et al., 1995) preferentially, and by doing so, alters structurally (via proline-rich stalk region) the organization of monomers, thus inhibiting the ability of this receptor to bind to sTNF. It appears that mTNF can control the quantitative balance of TNF-R1 and TNF-R2 in cells that express them, and that can have serious consequences for the outcome of the TNF response. Namely, when sTNF levels rise in circulation due to infection, sTNF actions in tissues would depend on the "imprint" left from previous interaction with mTNF.

The function of reverse signaling via mTNF- α is thought to be anti-inflammatory, probably in connection with secretion of IL-10 and TGF- β by the cell that signals in reverse (Kirchner et al., 2004; Pallai et al., 2016).

Membrane-bound mTNF and soluble sTNF have distinctive functions as indicated by knockout and knockin transgenic animal studies. It seems that mTNF can mediate a subset of beneficial TNF activities while lacking the systemic inflammatory effects of sTNF. One of the first functional consequences observed in mice deficient in both sTNF and mTNF is the lack of normal secondary lymphoid organ structure. These mice fail to form germinal centers upon immunization, are unable to mount host defense responses to infections (Pasparakis et al., 1996; Marino et al., 1997), and have none of the inflammatory responses known to be involved in models of brain-related autoimmune disease (*multiple sclerosis*) like *experimental autoimmune encephalomyelitis* (Körner et al., 1997). Targeted deficiencies in transgenic knockout mice of two ligand-two receptor systems (sTNF, mTNF, and TNF-R1 and TNF-R2 receptors) revealed an array of CNS effects and characteristics, which have been reviewed (Probert, 2015).

Fig. 3 Simplified TNF signal transduction and function. The proteins colored in blue are related to cellular distress or cell death, whereas the proteins in red are factors promoting cell survival. The resulting biological activities of TNF are indicated by blue (cell death) and red (survival) lines.

LT- β

In 1993, a novel LT- and TNF-like cytokine was discovered and was named LT- β . It could make heterotrimers with LT- α resulting with LT- $\alpha_1\beta_2$ complex (Browning et al., 1993) or LT- $\alpha_2\beta_1$ (Weinstein and Storkus, 2015) (Fig. 4). It prompted the reversal of the name TNF- β back into LT- α .

Several years later, the knockout mice revealed some cytokine functions (Koni et al., 1997).

LT- α (TNF- β) and LT- β are necessary for the development of secondary lymphoid tissue, and this requires the binding and activation of LT- β receptor (LT- β R) with the predominant form of LT- β , namely, LT- $\alpha_1\beta_2$ complex (Gubernatorova and Tumanov, 2016) (Fig. 4). LT- β R is required for the development of gut-associated lymphatic tissue (GALT), including Peyer's patches, mesenteric lymph nodes, and isolated lymphoid follicles. In the latter, T-independent IgA production occurs (as well as in the gut's mucous plate—lamina propria).

In LT- β R- and LT- β -knockout mice, there is a defect in IgA production in the intestine. It was demonstrated that T-cell independent IgA induction (via DC activation) depends on the LT- $\alpha_1\beta_2$ complex (TNF- β /LT- β_2) on ILC3 cells. However, soluble LT- α homotrimer (sTNF- β_3) secreted by ILC3 cells is necessary for T-cell dependent IgA induction in the intestinal lamina propria by promoting T cell migration to the gut (Kruglov et al., 2013; Kang et al., 2002).

The presence of LT- α (TNF- β) is necessary on the cell surface of lymphoid tissue inducer cells to interact with stromal cells (carrying LT- β R) during embryogenesis (Randall et al., 2008; van de Pavert and Mebius, 2010; Bar-Ephraim and Mebius, 2016).

Medical aspects

Production dysregulation of TNF has been implicated in a variety of human diseases. These include *Alzheimer's disease* (Swardfager et al., 2010), autoimmune diseases, major *depression* (Dowlati et al., 2010), and *cancer* (Locksley et al., 2001). Of autoimmune disorders, *rheumatoid arthritis* (RA), *juvenile RA*, *psoriasis*, *psoriatic arthritis*, *insulinitis*, and *inflammatory bowel disease* (IBD) have been linked to high levels of TNF (Keffer et al., 1991; Picarella et al., 1993; Victor and Gottlieb, 2002; Brynskov et al., 2002; Kontoyiannis et al., 1999; Neurath, 2014). Although *septic shock* involves high TNF levels, so far, it has not been seen as its dysregulation.

Fig. 4 Ligands and receptors of the TNF/LT family, their sources, and suggested function.

Monoclonal antibody (mAb) Infliximab (Remicade; Janssen Biotech, Horsham, PA, United States) was developed as a remedy to block TNF activity (Scallion et al., 2002) after animals' studies have shown benefit in the *rheumatoid arthritis* autoimmunity model. The introduction of infliximab in the clinics 20 years ago resulted in initial excitement because of successful treatment with lasting remission of many *rheumatoid arthritis* patients (reviewed in Melsheimer et al., 2019). Later on, several problems arose, including insensitive cases to TNF-treatment, but the most significant problem was immunization with the therapy. Namely, as the mAb needed to be repeatedly applied, rejection of the injected remedy occurred quite often, diminishing the clinical outcome in the end.

Also, constructs like Etanercept (Enbrel, Amgen) were made and approved for use in RA. Etanercept is a biologic comprising human TNF-R2 extracellular domain (for binding to TNF) that is attached to the human IgG1 constant region (to prolong serum half-life) (Scallion et al., 2002).

In the following years, novel TNF inhibitors, including humanized mAbs (Adalimumab, Humira; Golimumab, Simponi; and Certolizumab pegol, Cimzia) that efficiently bind and neutralize TNF were also developed (Kaymakcalan et al., 2009; Shealy et al., 2010).

Etanercept has been successfully used in RA patients. It is approved by the Food and Drug Administration of USA (FDA) to treat other autoimmune diseases such as *plaque psoriasis*, *psoriatic arthritis*, *polyarticular juvenile arthritis*, and *ankylosing spondylitis*.

Regarding *inflammatory bowel disease* (IBD), comprising *Crohn's disease* and *ulcerative colitis*, despite higher levels of TNF found in gut mucosa (Murch et al., 1991; Breese et al., 1994) and serum (Murch et al., 1991) of patients compared to a healthy population, its particular etiology and pathogenesis are still unclear as has been reviewed (Neurath, 2014). Recent advances point to ILC3 cells in gut mucosal homeostasis, which can be a double-edged sword because when ILC3 dysregulate, they can contribute to the progression and aggravation of IBD by overexpression of inflammatory cytokines IL-17, IL-22, and IFN- γ (Zeng et al., 2019). In animal models of IBD (reviewed in Gubernatorova and Tumanov, 2016), both TNF (sTNF and mTNF) were implicated in the disease (resembling mostly *Crohn's disease*), as blocking both forms of TNF led to stable continuous remission. Neutralization of mTNF seems crucial for treating experimental IBD *colitis* (Perrier et al., 2013). The therapy of *inflammatory bowel disease* using anti-TNF antibodies infliximab, adalimumab, golimumab, and certolizumab pegol has been a revolutionary improvement

(Tracey et al., 2008; Olesen et al., 2016; Ueda et al., 2013; Slevin and Egan, 2015). Unfortunately, one-third of patients have not responded to initial therapy, and up to 50% of patients ultimately have stopped responding (Nielsen and Ainsworth, 2013; Steenholdt et al., 2014).

Anti-TNF therapy has many systemic side effects, including those linked to infections and inflammation in the skin and joints (Tracey et al., 2008; Mocci et al., 2013). The most serious complication is the (re-)activation of latent *tuberculosis* (Cleynen and Vermeire, 2012). Other interesting side-effects of anti-TNF therapy are the Lupus-like syndrome and psoriasiform lesions, despite being anti *psoriatic* remedy (Mocci et al., 2013).

In the future, the receptor-specific antagonistic mAbs might be developed as treatment is specifically targeting TNF-resistant RA, MS or heart failure, or neurodegeneration.

The members of the large TNF-/TNFR-related superfamily are being targeted for treatments against human diseases or conditions such as *atherosclerosis*, *autoimmune* disorders, *cancer*, *osteoporosis*, and *transplant rejection*.

The IL-6 family

IL-6 is a product of activated T and B lymphocytes, monocytes and fibroblasts, and activated macrophages. IL-6 is produced after bacterial or viral challenge.

In innate immunity, the role of IL-6 is pro-inflammatory, stimulating the production of acute-phase proteins in liver cells, and in a concerted fashion helping in wound healing. The major function of IL-6 in the adaptive immune system is plasma cell differentiation as the final step of peripheral B lymphocyte development with antibody secretion.

Human IL-6 is a glycoprotein of 21–26 kDa, which contains 185 amino acids. The IL6 gene is located on human chromosome 7p21. IL-6 family of cytokines share four-helix bundle structures.

The receptors for the IL-6 family of cytokines have two polypeptides and are characterized by the presence of the shared transmembrane receptor subunit called gp130 (Fig. 5) or interleukin-6 signal transducer (IL-6ST, CD130) (Bravo et al., 1998; Bravo and Heath, 2000). Alternatively, some cytokine receptors in this group have a second chain very similar to IL-6ST. IL-6ST is a common signal-transducing chain for other cytokine receptors such as IL-11, IL-27, ciliary neurotrophic factor—CNTF, cardiotrophin-1—CT-1, cardiotrophin-like cytokine—CLC, leukemia inhibiting factor—LIF, neuropoetin (NPN), oncostatin M—OSM, and viral vIL-6 of Kaposi sarcoma associated herpesvirus HHV8 (Taga et al., 1992; Wang et al., 2009; Spangler et al., 2015). Receptors having chains similar to gp130 include IL-27R, IL-31R, G-CSF-R, LIF-R, OSM-R IL-12 β 1, and IL-12 β 2. These receptors have three structurally unique cytokine-binding sites on their cytokine ligands to assemble multimeric signaling complexes.

Fig. 5 Extended IL-6 family of cytokines characterized by shared four-helix bundle structure. In the middle, schematic representation of the ligand (IL-6) and its receptor comprising the gp130/IL-6 signal transducer (IL-6ST) chain and the IL-6R α chain (which can be solubilized, or trans-presented by a neighboring cell). These three molecules form a heterohexamer, which can signal into the cell. Each IL-6 family member can bind gp130 and additional specific receptor chain, or associate with biosimilars to gp130 (not shown).

Regarding the T-cell part of adaptive immunity, IL-6 is essential in forming the Th17 phenotype of helper T cells together with IL-1, IL-21, IL-23, and TGF- β (whereas IFN- γ , IL-2, IL-4, IL-12, and IL-27 can block their development). The hallmark of Th17 cells in the production of IL-17A, IL-17F, and IL-22 cytokines with neutrophil (granulocyte) mobilization.

IL-6 is also required for the development of Th22 helper cells, together with TNF (whereas TGF- β blocks their development). IL-6 can be secreted from some DCs, an action with which DCs can inhibit regulatory Treg cells' activity (and thereby, by suppression of suppression, they might activate helper T cells and, hypothetically, break tolerance).

Normal cells typically do not secrete IL-6. Secretion of IL-6 can be activated with the NF- κ B, a factor that is activated in many signaling pathways, including those by TNF and TLRs. Stimulation by bacterial LPS (that binds to TLR4) causes the secretion of IL-6 from monocytes and fibroblasts. Activated macrophages (with IFN- γ) also secrete IL-6.

Neutrophils that have migrated first to inflammatory sites do not release the receptor chain's membrane form (sIL-6R α) as previously thought. Instead, soluble sIL-6R α comes from the circulation (Schumacher et al., 2016). And this, in turn, activates the migration of pro-inflammatory cells and secretion of other mediators. Thus, soluble IL-6R α controls the IL-6 action (Fig. 5).

The trans-presentation or cluster signaling can happen across the thin divide between cells in close proximity when the IL-6R α anchored in the membrane of one cell binds to IL-6, and then together they attach to the gp130 fastened in the membrane of another cell.

Medical aspects

Increased serum concentrations of IL-6 and sIL-6R α were found in RA and juvenile forms of RA, which correlate with faster disease progression as well as the degree of joint destruction in RA. In *systemic juvenile RA*, sIL-6R was also significantly increased. Furthermore, osteoclasts produce large amounts of IL-6 in *Paget's disease*.

IL-6 is thought to play a role, along with other cytokines and factors, in the pathogenesis of *postmenopausal osteoporosis*, *Castleman's disease*, *multiple myeloma*, and *pituitary adenoma*.

Recently, in COVID-19 patients, high levels of serum IL-6 in the severe stage of the disease were detected, which was suggested to be an informative prognostic marker for severity (Santa Cruz et al., 2021).

Inhibition of IL-6 signaling pathway has potential to be used as treatment for many diseases. Anti-IL-6R α mAb tocilizumab (Actemra, Roche) has shown success in the clinical use of severe COVID-19 patients and some trials with autoimmune diseases. Sarilumab is also an IL-6R α binding mAb with inhibitory properties (Kevzara, Sanofi and Regeneron) that might be also used for the treatment of COVID-19 patients in severe cases. Furthermore, Sarilumab was approved as monotherapy (and in combination with methotrexate or other disease modifying drugs) for moderately to severely active *rheumatoid arthritis* in people who have not responded to, or did not tolerate, more conventional treatments (Burmester et al., 2017).

Cytokines with antiviral properties—Interferons

Interferons are proteins produced by many cell types in response to viral infections that can affect the uninfected neighboring cells thus, being an alarming signal for adaptive immunity and a mechanism for clearing the infection by preventing replication of particular viruses. Upon discovery over 60 years ago (Isaacs and Lindenmann, 1957), they were divided according to their properties like pH stability and antiviral potency (Wheelock, 1965; Stewart, 1980). Type I interferons are pH insensitive like IFN- α and IFN- β . However, pH-sensitive and 1000-fold less potent was type II interferon, so far with a single member—IFN- γ . In 2003, type III interferons were identified by genome analysis and named IFN- λ and they resemble type I in the potency of antiviral activity (Kotenko et al., 2003; Sheppard et al., 2003).

Type I interferons

Type I interferons are early molecular effectors capable of inducing an antiviral state in cells (Pestka et al., 1987). Originally classified as leukocyte (α) and fibroblast (β) IFN, novel advances led to their renaming. Although it was realized that almost all nucleated cells could produce IFN- α (Levy, 2002), its predominant source are plasmacytoid dendritic cells (pDCs).

Type I interferons comprise a large group of very similar proteins. In humans, the group includes 12 IFN- α , IFN- β , IFN- ϵ , IFN- κ , and IFN- ω . All members can bind to the single heterodimeric receptor IFN- α / β -R (encoded by IFNAR1/IFNAR2 genes) to exert their action, which is also ubiquitously expressed (Walter, 2020).

Genes encoding IFN- α / β members are located on human chromosome 9p22. There are over 20 known IFN alpha and the like genes, but only a single IFN- β gene—IFNB1.

The transcription of type I IFNs is stimulated by nuclear factor IRF7, a consequence of TLR3 signaling, which detects double-stranded RNA.

IFN- α R1/IFN- α R2 receptor signals via *Janus kinases* Jak1 and Tyk2 and these can, in turn, activate other factors like STAT-1, STAT-2, and IRF9 family of nuclear factors (Fig. 6). STAT-1 and -2, together with IRF9, constitute ISGF3 factor that can act on ISRE (interferon-stimulated response elements) in the genome and upregulate the expression of several hundred interferon-stimulated genes (Walter, 2020). The products of interferon-stimulated genes (ISGs) provide the biologic role of type I IFN.

Fig. 6 Signal transduction of type I interferons. IFN- α signals via IFN- α R1 (blue) and IFN- α R2 (green) receptor inducing *Janus kinases* Jak1 and Tyk2, and in turn, STAT family of nuclear factors.

The role of type I interferons is antiviral and immunomodulatory. The type I interferons have potent antiviral activities. IFN-type I stimulate both innate and adaptive immune responses, a characteristic which is shared with type III IFN, despite having a different receptor (Hoffmann et al., 2015). Type I IFNs can positively influence both cellular and humoral adaptive immunity.

Type I IFNs are produced rapidly following the infection with a virus. The anti-viral effects necessitate interaction with the receptor with consecutive induction anti-viral gene products such as ISG15, Mx proteins, OAS-ribonuclease and PKR enzyme. The ISG15 (IFN-stimulated protein of 15 kDa) has a role in the ubiquitin-like pathway. The Mx (myxovirus resistance) proteins have a role in surveying vesicle trafficking and preventing viral exocytosis. The 2',5'-oligoadenylate synthetase (OAS)-regulated ribonuclease L (RNase L) has a role in degrading single-stranded RNA in virus-infected cells. And, protein kinase R (PKR) has a role in inhibiting the translation of viral proteins (Sadler and Williams, 2008).

Type I IFNs enhance adaptive immune responses to viruses in numerous ways. In antigen-presenting cells (like DCs), they induce MHC class II molecules that would carry viral peptides and present them to cytotoxic CD8 T cells during priming. They also upregulate the co-stimulatory molecules (CD80/86) and initiate IL-15 synthesis in DCs (Fig. 9). Subsequently, the activation of DCs induces NK cells and T-cell proliferation and differentiation, with enhanced IFN- γ secretion (Tough et al., 1996; Sun et al., 1998; Kolumam et al., 2005; Surh and Sprent, 2008). Furthermore, type I IFN can directly promote expansion and differentiation of CD8⁺ T cells (Sun et al., 1998; Kolumam et al., 2005) and CD4⁺ T cells, like follicular helper (T_{fh}) cells (Loetsch et al., 2017). The T_{fh} cells help B cells in germinal centers within secondary lymphoid organs to differentiate into plasma cells and secrete specific antibodies that can neutralize the virus. The timing of type I IFN production seems to be critical for its successful influence on adaptive immunity.

Medical aspects

IFNs are used therapeutically, with the most significant example being the treatment of *hepatitis C virus* (HCV) infection, and they are also used against various other disorders, including numerous malignancies and *multiple sclerosis* (Borden et al., 2007). For example, IFN- α is used in therapy against *hairy cell leukemia*, *malignant melanoma*, and AIDS-related *Kaposi's sarcoma* under IFN Alfacon-1 (Advaferon, Infergen) as listed in DrugBank (Wishart et al., 2018, Drugbank, 2021).

IFN- α/β are essential for human anti-HSV-1 immunity in the CNS, as immunodeficiency of type I receptor (hereditary IFNAR1-null mutation) can lead to *encephalitis* caused by *herpes simplex virus-1* (Zhang et al., 2008; Bastard et al., 2021a).

Additionally, autoantibodies (auto-Abs) against IFN- α/β have been detected in some other pathological circumstances. High titers of circulating auto-Abs against at least 14 of the 17 individual type I IFNs were found in some recipients of the *yellow fever*

Fig. 7 The signal transduction of IFN- γ involves Jak/STAT pathways and MAPK/PI3K/Akt.

vaccine. These antibodies were recently shown to underlie at least 10% of cases of life-threatening COVID-19 pneumonia. The auto-Abs were neutralizing in vitro, blocking the protective effect of IFN- α 2 against Yellow fever vaccine strains (Bastard et al., 2021b).

Moreover, auto-Abs to type I IFN resemble a functionally hereditary lack of genes involved in type I IFN signal transduction. Such auto-Abs have been found against other cytokines, including anti-IL-6 in patients with the *staphylococcal* disease, against IFN- γ in *mycobacterial* disease, and against IL-17A/F in *mucocutaneous candidiasis* (Bastard et al., 2020). Such individuals are likely at higher risk of acquiring life-threatening not only COVID-19 but also other viral or bacterial diseases, including adverse effects of vaccinations in general.

Type II interferons

IFN- γ is the sole member of type II interferon kind. Its activity includes antiviral, but it is a 1000-fold lower than that of other types of interferon. The major role IFN- γ has is in regulating adaptive immunity.

IFN- γ is a homodimer (Yphantis and Arakawa, 1987). It binds to two different transmembrane receptor molecules in forming a heterohexamer (Fig. 7). The α -receptor chain, IFN- γ R1, is constitutively expressed on all nucleated cells and, historically, was the first cytokine receptor molecularly cloned and analyzed (Aguet et al., 1988). On the other hand, the β -receptor chain, IFN- γ R2, is expressed in a more restricted fashion and is tightly regulated. This feature of the receptor confers receptiveness to the ligand (Bach et al., 1995; Pernis et al., 1995; Tau et al., 2001) and has major consequences, especially in peripheral T helper cell development.

IFN- γ has a weak antiviral activity (Walter, 2020). One of the most important actions of the IFN- γ is activating macrophages and dendritic cells and inducing or enhancing the MHC molecules' expression to enhance the presentation of viral, bacterial, parasitic, or tumor antigens to T cells. In Fig. 8, some of the essential activities of the IFN- γ are listed. The full list of induced genes is accessible in databases like WikiPathways or NetPath.

The naïve T cells are usually localized in the immune system's periphery (secondary lymphoid tissue like lymph nodes and spleen). Upon encountering a pathogen in infected and usually damaged tissue, local dendritic cells pick up this destructed mixture of proteins, mature, and re-locate to the paracortex of draining lymph nodes via lymphatics. There they meet naïve and quiescent memory T cells of the helper kind. Then they present antigens to the T cells. In detail, when a particular T cell bind (using its T-cell receptor, TCR) with sufficient affinity to the peptide-loaded MHC class II molecules on DCs, such naïve CD4 T cell can differentiate further into one of the classes depending on the cytokine environment (and perhaps some putative additional signals) including Th1 type characterized by T-bet signature, and by producing IFN- γ (Dembic, 2015a).

Fig. 8 IFN- γ is the macrophage activating factor and polarizing cytokine for Th1 response. Only actions on macrophages are shown. M ϕ : quiescent (not activated) macrophage; aM ϕ : activated macrophage. I & II: MHC class I and class II molecules. Adapted from Dembic Z (2015a) (Chapter 5) Cytokines of the immune system: Interferons. In: Dembic, Z. (ed.) *The Cytokines of the Immune System*. Amsterdam: Academic Press. Chapter 5 with permission.

IFN- γ plays an important role in guiding the development of Th1 response and inhibits the formation (induces apoptosis) of other types like Th2, Th9, Th17, and Tregs. The Th1 cells downregulate the IFN- γ R2 and achieve an IFN- γ resistant state (Pernis et al., 1995), which is likely the reason for their survival.

IFN- γ is also a master checkpoint regulator for many cytokines. It operates via an autocrine mechanism to elevate STAT1 and induce internalization of gp130, a common component of many cytokine receptors. This targeting of a receptor subunit common to many members of an otherwise diverse family of cytokines indicates how a master regulator can control so many diverse receptors (Zha et al., 2017).

Type III interferons

Type III IFNs play a similar role as type I IFN and are especially important at airway epithelial surfaces (Crotta et al., 2013). In addition to their antiviral activity against hepatitis C virus, they have an immunomodulatory role. Type III IFNs comprise four members: IFN- λ 1 (IL-29) and IFN- λ 2, IFN- λ 3 (IL-28A, IL-28B), and IFN- λ 4 (Prokunina-Olsson et al., 2013).

IFN- λ s are small proteins conformationally similar to type I IFNs (Mendoza et al., 2017). The heterodimeric IFN- λ R1/IL-10R β receptor, upon binding the ligand, activates Jak1 and Tyk2 kinases, leading to the initiation of IFN-mediated signaling cascades. Thus, type III IFNs signal via the same STAT-1/STAT-2/IRF9 complex (ISGF3) as type I IFNs to exert antiviral activity (Zhou et al., 2007). A review has been recently reported about the structural organization of ligand-receptor complexes and their signaling, comparing all three types IFNs (Walter, 2020).

Cytokine storm (and COVID-19)

The *cytokine storm* is a hyperinflammatory condition triggered by infection (bacterial septic shock or viral load in COVID-19) and characterized by a systemic and persistent increase in many cytokines. Here, it will be discussed mainly in relation to COVID-19.

Biology

The septic shock can be caused by superantigens, endotoxins, exotoxins, or possibly other molecules produced by an infectious agent(s), which penetrate tissues and ultimately enter a victim's circulation. The infection site (usually respiratory, urogenital, or gastrointestinal tract) gets an influx of immune cells such as monocytes, dendritic cells, macrophages, neutrophils, and T cells from the circulation (*hemophagocytic lymphohistiocytosis*).

Fig. 9 Adaptive immunity responses to viral infection like SARS-CoV-2. The schematic representation of cellular and molecular events in the secondary lymphoid tissue like the cortex and paracortex of lymph nodes (LN). BCR, B cell receptor; TCR, T cell receptor; MHC, Major histocompatibility complex.

The immune dysregulation seen in septic shock is likely triggered by a particular programmed cell death called pyroptosis. Pyroptotic cell death induces an abundance of cytokines produced locally, including IL-1, IL-2, IL-6, IL-7, IL-10, interferon- γ -induced-protein-10 (IP-10), monocyte chemoattractant protein 1 (MCP-1) alias C-C motif chemokine ligand (CCL2), macrophage inflammatory protein (MIP)-1 α also known as CCL3, and TNF- α .

These events can further lead to tissue destruction by breaking endothelial cell-to-cell interactions, damage of vascular barrier, an increase of capillary permeability, neutrophil and cytotoxic T cell recruitment, production of oxygen free radicals, and leukotrienes (Vardhana and Wolchok, 2020) with consequential multiorgan failure and death (Huang et al., 2020; Bhaskar et al., 2020; Tleyjeh et al., 2021).

This scenario is typical for the *septic shock*, and it resembles the cytokine storm encountered in COVID-19. The critical part is still unclear, namely, why the immune system dysregulation happens, or was it there from the start and only uncovered by the “terrible” virus?

Clinical history of COVID-19

Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) is a single-stranded positive-strand RNA virus that infects humans, birds, and some other vertebrates. It belongs to the Coronaviridae (CoV) family, Nidovirales order. CoVs are further divided into four categories: α , β , γ , and δ (Peck et al., 2015). COVID-19 disease is a consequence of infection with SARS-CoV-2 beta-coronavirus. The virus caused a world pandemic infecting within a year and 4 months over 150 million people with over 3 million deaths (Worldometer, 2021).

The virus probably emerged in late 2019 in Wuhan (China). The phylogenetic trees are shown on the Nextstrain site—a database maintained by the dedicated team (Nextstrain, 2019), depict evolutionary relationships of SARS-CoV-2 virus variants from the ongoing COVID-19 pandemic. There are hundreds of thousands of genome sequences of SARS-CoV-2 available. However, only around 3000 are shown on the site, pointing to the mutated virus’s major substrains (starting with the Wuhan strain as number 1). Its mutation rate seems to be around 8×10^{-4} substitutions/site/year (Nextstrain, Hadfield et al., 2018). In other words, in the genome of SARS-CoV-2 (about 30 kB) 24 mutations are expected per year.

COVID-19 is divided into three clinical stages concerning severity and prognosis (Siddiqi and Mehra, 2020; Romagnoli et al., 2020). First of all, 43% of those infected have no symptoms at all (Gudbjartsson et al., 2020a; Lavezzo et al., 2020), but can infect others because they shed the virus 15–25 days (median 19) after they got infected (Long et al., 2020). People with symptoms go through three stages of the disease. In the first stage (I), some mild symptoms usually prevail (headache, dry cough, myalgia, or sub febrility). These can occur between 2 and 14 days after infection (with a median of 6 days), probably depending on the viral load. The second stage (II) presents with dyspnea, cough, and high fever within a week or two. Clinical examination shows abnormal thoracic radiographic imaging, and blood tests show lymphopenia and raised levels of inflammatory markers, including cytokines (more details follow below). The second stage is further divided into two substages, relating to the absence (IIa) or presence (IIb) of hypoxemia. Lastly, the third stage (III) is characterized by clinical manifestations of the cytokine storm (systemic inflammatory syndrome), culminating in severe lung failure with an ominous prognosis.

About 14% of COVID-19 patients develop a severe form of the disease, while most develop only mild symptoms. Some 5% become critically ill with respiratory failure and multiorgan damage (Wiersinga et al., 2020). Those with co-morbidities have a higher risk for death in severe stages. So far, indices report 2–3% deaths in over 100 million closed cases (Worldometer, 2021). It seems that widespread damage caused by the cytokine storm is proportional to the severity of COVID-19 (Del Valle et al., 2020). The risk of death from infection is 0.3% (infection—fatality ratio) in Icelanders, and it is similar to those in the US (Gudbjartsson et al., 2020b). This is about three times higher than influenza. However, higher infection rate and more deadly outcome are feared in infection with the UK (B.1.1.7; alpha), South African (B.1.351; beta), Brazilian (P.1; gamma), or Indian (B.1.617.2; delta) strains of the SARS-CoV-2 virus.

Those that were diagnosed with COVID-19 developed neutralizing antibodies against the virus. The humoral immune response initially peaked but subsided within several weeks after clearing the virus. Then another protective wave of neutralizing antibodies takes over and probably lasts much longer, as we have observed for similar viral diseases. In fact, 91% of people who tested positive for the infection with SARS-CoV-2 had such protective antibodies 4 months after initial diagnosis (Gudbjartsson et al., 2020b).

Post-acute sequelae of COVID-19 (PASC)

In about 10% of patients with COVID-19, symptoms like fatigue, shortness of breath, “brain fog,” and chest pain do not resolve in subsequent months (Carfi et al., 2020). These after-effects are referred to as post-acute sequelae of COVID-19, or PASC. The long-lasting health effects of SARS-CoV-2 infection can lead to some severe clinical complications.

The culprit for PASC might be several: (1) First, viral persistence because 4 months after acute disease, the virus was found alive in biopsies of gastrointestinal mucosa in third of patients (Gaebler et al., 2020). (2) Then, PASC could be the long-lasting effect of the virus (similar to late consequences of Ebola, CMV or EBV). (3) The next possibility is the upsurge of autoreactive antibodies and autoimmunity that could develop alongside the protective immune response to SARS-CoV-2 and cause widespread damage (Zuo et al., 2020; Ehrenfeld et al., 2020). An example is that neutralizing autoantibodies against type I and type III interferons were found in about 10% of patients with the life-threatening disease (Bastard et al., 2021b).

The latter explanation was also suggested to be the main cause for severe COVID-19 disease. It is endorsed by the fact that persons with hereditary lack of key proteins in the type I/III interferon signaling system have been shown to have a higher risk of viral diseases and can show adverse effects after vaccinations (Bastard et al., 2020, 2021a,b), indicating that hereditary dysregulation in the innate immunity can lead to severe COVID-19 and PASC in survivors.

And, lastly, PASC is not necessarily correlated with disease severity.

Immune responses in COVID-19

Infection with SARS-CoV-2 usually starts by airborne virus invading cells of the upper respiratory tract. The virus achieves this by first binding to angiotensin-converting enzyme (ACE)2 and transmembrane serine protease (TMPRSS)2 on the respiratory epithelium (Hoffmann et al., 2020). Upon entry, SARS-CoV-2 binds to Toll-like receptors (TLR)3 and TLR7 in endosomes and in the cytosol to retinoic-acid-inducible gene I (RIG)-like receptors (RLRs), which engage with the mitochondrial antiviral signaling (MAVS) protein (Seth et al., 2005). These actions recruit nuclear factors like interferon regulatory factor (IRF)3, IRF7, AP-1 and NF- κ B to stimulate the production of type I and type III IFNs, and pro-inflammatory cytokines IL-1, IL-6 and TNF- α (Takeuchi and Akira, 2010).

IFN- α/β binds to heterodimeric IFN- α/β R (Fig. 6), which signals via Jak1/Tyk2 and STAT1/STAT2/IRF9 pathway leading to induction of interferon-stimulated genes. The latter encode enzymes like 2'-5'-oligoadenylate synthetase 1 (OAS-1), OAS-2, OAS-3 and protein kinase R (PKR), critical for innate immunity (Pico et al., 2020). The OAS enzymes activate latent RNase L, which can degrade any intracellular RNA resulting in the inhibition of viral replication.

Further, type I IFNs stimulate adaptive immune responses to SARS-CoV-2 (and others) in many ways. In antigen-presenting cells like DCs (Fig. 9), IFN- α/β enhances antigen presentation to T cells via enhancement and induction of the expression of MHC class I and class II molecules, respectively. DCs, in turn, can activate cytotoxic CD8 T cells specific for viral peptides presented on them. Prompted by the type I/III IFN, DCs upregulate the co-stimulatory molecules (CD80/86) and initiate IL-15 synthesis. In the next step, the activated DCs induce NK cell activation with enhanced IFN- γ secretion (Tough et al., 1996; Sun et al., 1998; Kolumam et al., 2005; Surh and Sprent, 2008). Furthermore, type I IFNs promote expansion and differentiation of CD8⁺ T cells (Sun et al., 1998; Kolumam et al., 2005) and CD4⁺ T cells, like follicular helper (T_{fh}) cells (Loetsch et al., 2017). The T_{fh} cells help B cells in

germinal centers within secondary lymphoid organs to differentiate into plasma cells and secrete specific antibodies that can neutralize the SARS-CoV-2 virus. The timing of type I IFN production seems to be critical for their beneficial influence on adaptive immunity (Fig. 9).

Through these initial steps in activating innate and adaptive immunity, the SARS-CoV-2 virus can be easily eliminated from the body. However, since it does not happen readily in all infected persons, and some might die without clearing the virus, we wish to understand why. The methods to realize this are observations and analyzes of clinical data and laboratory findings of affected patients, including cytokines.

It seems that the timing of the interferon response is crucial for a successful outcome. SARS-CoV-2 can induce IFN- β and type III IFNs; however, its effect *in vitro* is weaker or delayed than other coronaviruses with similar tropism (Blanco-Melo et al., 2020; Chu et al., 2020). Coronaviruses can evade innate immunity during the infection in humans, probably due to increased viral load within the first 10 days. Higher viral load is associated with widespread inflammation and increased severity of the disease (Sariol and Perlman, 2020). Furthermore, a reduced percentage and counts of circulating ILCs were found in COVID-19 patients, with a particularly interesting drop in frequencies of ILC2 cells in severe but not moderate disease, suggesting that they indicate disease severity (García et al., 2020).

In patients with moderate and severe COVID-19, very low production of IFN- β (and insufficient ISG induction) was observed (Blanco-Melo et al., 2020). However, this was contradicted by others that found the opposite (Del Valle et al., 2020; Wilk et al., 2020). Yet, the 30-kb genome of SARS-CoV-2 encodes several accessory proteins (N, ORF6, ORF8 and ORF3b) that can strongly inhibit the induction of type I IFNs, and ORF3a protein can reduce the quantity of IFN- α R on the cell surface (Li et al., 2020; Sa Ribero et al., 2020; Konno et al., 2020). Another fact is that SARS-CoV-2 is sensitive to exogenous type I IFN *in vitro* (Lokugamage et al., 2020). Given these arguments, and assuming the high mutation rate of the SARS-CoV-2 virus (10^{-8} changes/site/year Nextstrain, 2019), it is possible that differences in the above-mentioned controversial studies are related to distinctive substrains of the virus or unknown difference in the genetic background of the patients, as there were too few analyzed samples (Blanco-Melo et al., 2020; Wilk et al., 2020; Del Valle et al., 2020).

The SARS-CoV-2 elicits in most people neutralizing antibody response. As these circulate and clear the virus, the cells that get infected can only be eliminated by CD8 cytotoxic T cells (CTLs) specific for viral antigenic peptides (within the MHC class I molecules on target cells). These CTLs have a major role in the antiviral response (Fig. 9). In severe COVID-19 patients, there is a pronounced diminished frequency of CTL in the blood. Among these inadequate numbers of T cells, CTLs often have an exhausted phenotype, expressing PD-1, which is a marker of ineffective immunity. The number of T cells rises after recovery (Ruan et al., 2020; Sun et al., 2020).

However, in the fatal cases, a hypothesis has recently been upheld that the inhibition of type I (and III) IFNs by the SARS-CoV-2 virus in some individuals might lead to severe COVID-19 because of the power balance shift. Namely, the power in inducing adaptive immunity has changed for the worse. In such a scenario, DCs would produce less IL-15, and in turn, fewer T-follicular helper (Tfh) cells would be generated (to help B cells and hence fewer neutralizing antibodies), as well as reduced numbers of ineffective CTLs (with PD-1 phenotype) would not eliminate virus-infected cells (Fig. 9). The result would be the stage with continued, persistent, and ominous production of pro-inflammatory cytokines such as IL-1, IL-6, and TNF- α from infected monocytes and macrophages—or the *cytokine storm* (King and Sprent, 2021).

Cytokines in COVID-19 patients

Detailed analyzes of numerous cytokines in COVID-19 patients revealed higher plasma levels than healthy adults of IL-1 β , IL-1Ra, IL-7, IL-8 (CXCL8), IL-9, IL-10, Fibroblast growth factor (FGF), Granulocyte-colony stimulating factor (G-CSF), Granulocyte-Macrophage-CSF (GM-CSF), Interferon- γ (IFN- γ), CXCL10, CCL2, CCL3, MIP-1 β (CCL4), Platelet-derived growth factor (PDGF), TNF- α , and Vascular endothelial growth factor (VEGF). Some cytokines like IL-5, IL-12p70, IL-15, Eotaxin (CCL11), and RANTES (CCL5) were not elevated (Huang et al., 2020). Interestingly, severe COVID-19 patients (in the intensive care unit) showed even higher plasma concentrations for IL-2, IL-7, IL-10, G-CSF, CXCL10, CCL2, CCL3 TNF- α than the non-intensive care unit patients (Huang et al., 2020; Bhaskar et al., 2020).

Others identified, besides the IL-1 β , IFN- γ , MIG (CXCL9), CXCL8, CXCL10, CCL2, and TNF- α , also IL-6, IL-12, and TGF- β in the early phase of the disease. In the late stage of COVID-19 disease, IL-2, IL-10 and TGF- β were elevated, whereas in the disease with fatal outcome, only CXCL9, CXCL8, CXCL10, and CCL2 were detected with higher levels. In the lung tissue, massive infiltration of pro-inflammatory cells, including T helper-17 (Th17) lymphocytes, have been found by *postmortem* examination (Tang et al., 2020).

The most recent report points to the correlation between increased serum IL-6 levels and respiratory failure in COVID-19 pneumonia. According to these authors, quantification of IL-6 levels during various stages of the disease could discriminate between survivors and non-survivors, which may be useful for prognosis and treatment (Santa Cruz et al., 2021). However, not all fatalities can be ascribed to the cytokine storm. High titers of circulating auto-Abs against type I IFNs were shown to be associated with at least 10% of cases of life-threatening COVID-19 pneumonia (Bastard et al., 2020).

In conclusion, IL-6, IL-8, and TNF- α are independent biomarkers regarded as essential for the prognosis of COVID-19 severity (Del Valle et al., 2020), thus shaping potential treatment methods (Fig. 10).

Fig. 10 Cytokine storm in COVID-19 and potential treatments. Adapted from Ye Q, Wang B and Mao J (2020) The pathogenesis and treatment of the 'Cytokine Storm' in COVID-19. *Journal of Infection* 80: 607–613, with permission.

Genetic risk

Risk factors for life-threatening COVID-19 pneumonia are gender (male), age (elderly), and having other medical conditions (comorbidity) (Bastard et al., 2020).

Regarding prognosis, it is noteworthy that genetic (hereditary) polymorphisms in some cytokine and cytokine receptor genes can modulate variations in infection- or vaccine-induced cytokine responses (Morel and Turner, 2010). Some could lead to a hyperreactive state like cytokine storm, but the exact causative relationship remains unclear.

Recent research showed several genetic risk factors in causing severe COVID-19 disease. The first is the type I interferon receptor gene *IFNAR2* coding for the IFN- α/β receptor second chain (Fig. 6). Other predisposing genetic factors for COVID-19 include genes that code for antiviral restriction enzyme activators (*OAS1*, *OAS2*, and *OAS3*), *TYK2*, encoding a tyrosine kinase (implicated in signal transduction of several cytokines), and the dipeptidyl peptidase gene *DPP9*. Further analysis revealed a causal link between severe COVID-19 disease, low expression of *IFNAR2*, and high expression of *TYK2*. Lastly, a transcriptome-wide association study showed the monocyte/macrophage chemotactic receptor *CCR2* associated with severe COVID-19, too (Pairo-Castineira et al., 2020). Perhaps, people with such defects should be singled out and taken care of in preventing infection, not only with the SARS-CoV-2, as they might not be eligible for vaccinations.

Therapies

Treatment for COVID-19 disease (illustrated in Fig. 10) involves specific therapies like antagonizing biologics, including receptor antagonists, monoclonal antibodies (mAbs) directed to cytokine-receptor interaction (anti-IL-6, anti-IL-1, anti-GM-CSF, and anti-TNF- α) to prevent its action, and small molecules that could inhibit signal transduction. Non-specific treatments include hormones like corticosteroids that counteract cytokines' actions and re-purposed drugs previously used in treating other diseases (reviewed in (Badary, 2021; Ye et al., 2020).

mAbs used, so far, in the treatment of COVID-19 are anti-IL-6-receptor, tocilizumab (Actemra, Roche) and Sarilumab (Kevzara, Sanofi & Regeneron), and anti-IL-6 mAbs like olokizumab (R-Pharm) and siltuximab (Sylvant, EUSA Pharma and BeiGene)

(Badary, 2021). Further, mavrilimumab (anti-GM-CSF) and (PD)-1/PD-L1 checkpoint inhibition ones (pembrolizumab, nivolumab) are also considered. So far, anti-IL-6 therapies yielded mixed results, but treatment with anti-IL-6R α *tocilizumab* may reduce the risk of invasive mechanical ventilation or death in patients with severe COVID-19 pneumonia in randomized controlled trials (Kewan et al., 2020; Tleyjeh et al., 2021). Moreover, bevacizumab (a VEGF-inhibiting mAb) also showed promise recently in treating severe COVID-19 patients (Pang et al., 2021).

Regarding anti-IL-6R α therapy with *tocilizumab*, some argue that Vitamin D has advantages. Namely, *tocilizumab* non-selectively blocks both anti-inflammatory and pro-inflammatory actions of IL-6 and Vitamin D reduces IL-6 production (by immune cells), thus reducing only pro-inflammatory effects of IL-6 (Silberstein, 2021).

Other therapies used antiviral agents (remdesivir), cytokine adsorption devices, antimalarials (chloroquine, hydroxychloroquine), antibiotics (azithromycin), intravenous immunoglobulin (IVIG) from immune donors, and other small molecules (Tang et al., 2020; Badary, 2021).

Antiviral agents like remdesivir have shown success in treating COVID-19 (Buckland et al., 2020).

It seems that antimalarials were effective against SARS-CoV-2 because they inhibit the production and release of IL-6 and TNF, potentially preventing the cytokine storm (Yao et al., 2020). They can also work in synergy with azithromycin (Gautret et al., 2020). Still, the US Food and Drug Administration (FDA) revoked its approval due to adverse effects, showing that the drug's potential benefits may not outweigh its known and potential risks (FDA, 2020), and azithromycin could have an additive effect on the adverse effects of hydroxychloroquine.

Dexamethasone was also shown to reduce COVID-19-associated mortality (Recovery, 2020), as corticosteroids can reduce cytokines' uncontrolled expression during the COVID-19's cytokine storm.

Anakinra is a biologic medicine (IL-1 receptor antagonist, IL-1Ra) that inhibits the IL-1 α and IL-1 β . It has been used to treat *rheumatoid arthritis* in combination with methotrexate. Anakinra has been used with some success in several small studies in patients with COVID-19 (Cavalli et al., 2020). An overall strategy in COVID-19 therapies regarding the cytokine storm is depicted in Fig. 10.

It is not known what are the effects of these remedies on PASC patients.

Prevention

Over 200 vaccine candidates are underway to prevent the development of COVID-19 disease (World Health Organization, Coronavirus disease web site, Nature briefings). Some countries have already approved vaccines that use SARS-CoV-2 mRNA encoding spike protein (that binds the angiotensin receptor helping the virus penetrate and infect human cells) with 90–95% protection (Pfizer/BioNTech, International, and Moderna, United States). Similar technology (mRNA encapsulated in lipid nanovesicles) was also used to produce CureVac (Belgium and Germany) vaccine, underway in phase 3 trials.

Other vaccines use non-replicating types of adenovirus as vectors carrying SARS-CoV-2 spike antigens encoded in its DNA. For example, the *Covishield*, produced by Oxford University and Astra-Zeneca (UK, US, Brazil, and South Africa), is a chimpanzee adenovirus (ChAdOx5) based vaccine. It has lower protection (around 70% in a single dose) against severe disease, but if applied in two dosages separated more than 3 weeks apart, the protection could increase to comparable levels. It can protect against B.1.1.7 type of SARS-CoV-2 (the UK variant), but not against South African B.1.351 type (Nature briefings, update 25, March 2021). Novel formulations are under development that would be able to do so in the future. Oxford-AstraZeneca vaccine might be preferable for use because it is cheap and can be stored at 2–8 °C (while the other, mentioned so far, need deep-freezer conditions).

Some vaccines use human adenovirus types Ad5 and Ad26; for example, Johnson & Johnson (International) vaccine uses Ad26. It is approved for a single-dose use. The vaccine was 66% effective at preventing moderate and severe COVID-19 at 28 days after vaccination including all countries and variants, but 85% effective at preventing severe or critical disease. When split by country, the vaccine was 72% effective in the U.S., 66% effective in Latin American countries and 57% effective in South Africa at preventing moderate to severe disease at 28 days (Nature briefings).

On the other hand, CanSino Biologics and the Academy of Military Medical Sciences (China, Canada, Russia and Saudi Arabia) uses Ad5 in a single-dose regimen with 90% efficacy in preventing severe disease. Interestingly, Gamaleya Institute, Health Ministry, and "Acellena Contract Drug Research and Development" (Russia) uses Ad5 in the first injection, followed by Ad26 type in the second dose of the vaccine known as *Gam-COVID-Vac*, or *Sputnik V* and reported over 90% prevention of severe disease.

Vaccines like *Valneva* (France and Austria) and several Chinese-based producers, including *SinoVac Biotech* (China, Brazil, Bangladesh, and Indonesia), Wuhan Institute of Biologic Products with Sinopharm (China and UAE), and Beijing Institute of Biologic Products with Sinopharm (China) use previously established protocols for vaccinations with inactivated SARS-CoV-2 virus. Valneva's vaccine *VLA2001*, currently in phase 3 in Europe, consists of inactivated whole virus particles combined with two adjuvants, alum and CpG1018. Preclinical experiments with this adjuvant combination showed higher antibody levels than single adjuvant formulations, including the Th1 type immune response development. The novel CpG1018 adjuvant has previously been used to prepare the recently FDA-approved hepatitis B vaccine (HEPLISAV-B).

Novavax, a biotechnology company supported by Glaxo-Smith-Kline (GSK) and the UK government, produced a COVID-19 vaccine (Australia and South Africa), that contain nanoparticles carrying antigens derived from the SARS-CoV-2 spike protein (with Matrix-M adjuvant). It demonstrated around 90% efficacy against most types of the virus (but only 50% against B.1.351 South-African type) according to Phase 3 trial in the UK in the beginning of 2021 (DDW, 2021).

In addition, Shenzhen Geno-Immune Medical Institute (China) is testing a novel approach using immune cells (human dendritic cells and T cells, or artificial antigen-presenting cells) that are engineered to express a synthetic minigene based on

SARS-CoV-2 proteins and injected or infused into the patient. In detail, the dendritic cells previously taken out from the patient's blood are incubated in cell culture in order to introduce SARS-CoV-2 antigens into them (using a lentiviral vector) and then returned to the patient. The aim is to stimulate the correct T cell helper response (likely Th1) that would be beneficial in preventing COVID-19.

The immune response and inflammation caused by SARS-CoV-2 virus infection, as well as the variety of COVID-19 clinical consequences, were recently extensively reviewed (García, 2020).

The side effects are usually mild, start during the first days after vaccination, and stop within the following few days. Majority reports low pain sensation at the site of injection. Other usual side effects include weakness, headache, muscle pain, freezing feelings, joint pain and fever. They are more frequent after the second dose. Rare side effects that are serious include thrombosis - blood-clotting ($1:10^5$ – $1:10^6$) which can lead to stroke or heart attack. The possible reason for these events is a rare occasion when DNA from the vaccine forms with proteins like tissue factor (a coagulation factor) an immunogenic complex (in some persons for unknown reasons). The latter can provoke the generation of auto-antibodies against this factor. When tissue factor binds to platelets, autoantibodies can start coagulation by activating them. Thus, increased blood clotting tendency can occur in some individuals, but the reason for making such auto-antibodies is still unclear. Furthermore, if *disseminated intravascular coagulation* develops (like in the septic shock), then the complete consumption of coagulation factors and depletion of fibrinogen in the blood would lead to overall bleeding. Recent surveys show that vector-based vaccines have reportedly 20–30 times higher bleeding incidents than mRNA-based ones. The reasons for bleeding incidents might be due to aptamer formation between vector DNA and some of the coagulation factor cascade proteins or their regulatory ones in some individuals thereby preventing (or prolonging) hemostasis.

Concluding remarks

We cannot predict how long vaccine protection would last; we can only infer it from the observation. Similarly, we cannot predict how would the immune system combat cancer. We observed that it could win in some 20% (to at best 40%) of treated cancer patients, and the success rate is correlated with the type of cancer (Dembic, 2020). Furthermore, we cannot predict with certainty how successful our treatments will be in stopping autoimmune diseases or curing allergies. We do not have a treatment to tolerate transplanted organs without immune-depressants, yet, the nature has provided a (perhaps complex, but finite) solution each time a child is being carried by its mother. The reason why we cannot predict and find correct treatments is simple—we still lack knowledge to form a unifying theory on immunity.

We have quite a few models starting with the Self-nonsel self discrimination (Bretscher and Cohn, 1970; Cohn, 2006; Cohn et al., 2019), the Pathogenicity (Janeway, 1989; Medzhitov and Janeway, 2000), the Danger (Matzinger, 1994, 2007), the Co-stimulation and co-inhibition (Sinclair and Anderson, 1994, 1996), the Ignorance (Zinkernagel, 1996), and the Integrity (Dembic, 1996, 2000, 2015b, 2019) model, but we could not use them so far for predictive and preventive purposes, or at least not reproducibly in most cases. Perhaps, inventing more models about the inner workings of the immune system would help like the most recent example in which the immune system employs quorum sensing to act and regulate its responses (Butler et al., 2013; Bosch et al., 2017; Al-Yassin and Bretscher, 2018; Postat and Bousso, 2019; Schrom et al., 2020). A quote from the famous British statistician, George E.P. Box, says “Essentially, all models are wrong, but some are useful.” Then, perhaps, we only need more time for the useful concept to emerge.

Maybe this pandemic helped make the awareness about what we can do and what we cannot: however, if we invest in science for our collective health, the goal would be reachable perhaps in our lifetimes. The success would save humanity from another, perhaps even more deadly, pandemic in the future (we know from the history of plague that such scenario is possible). Should we invest in deciphering the immunity with more vigor? I strongly advocate this pathway. Conceivably, some funds could be used to make computer-aided predictions about the immune system's working in healthy and diseased.

These past achievements would not have been possible without the groundbreaking research of the heroes in science working and giving their lives for the cause in previous decades and centuries. And although, superficially, biomedical science looks like a never-ending story—I believe in the happy ending—we only have about 20 thousand genes, and that is not an *infinite* but *useful* number (to start with computer-aided predictions).

Chemokines

Chemokines are a group of small, secreted molecules known for stimulating directed communication and migration of various cells via signaling through G-protein coupled receptors (Bachelier et al., 2013). In humans, the genes encoding chemokines are found on chromosomes 4 and 17 (Zlotnik et al., 2006; Nomiya et al., 2010). In their primary amino acid sequence, the arrangement of important cysteine residues connected with disulfide bonds forms the conserved chemokine fold and constitutes the basis for the nomenclature and classification of chemokines (Miller and Mayo, 2017; Hughes and Nibbs, 2018). The systematic nomenclature introduced in 2000 is based on the structure of the two cysteines closest to the N terminus which can be directly juxtaposed (CC), separated by a single amino acid (CXC) or by three amino acids (CX₃C) (Murphy et al., 2000). Certain chemokines lack the first cysteine residue and are known as XC chemokines (Kennedy et al., 1995). Structurally, a chemokine monomer consists of a central three stranded β -sheet, an overlying C-terminal α -helix, and a short unstructured N terminus which plays a critical role in receptor activation (Miller and Mayo, 2017). The rigid loop, the N-terminus and the glycosaminoglycan (GAG) binding sites within the β -strands or in the C-terminus are considered important domains for chemokine functions (Rossi and Zlotnik, 2000). Chemokines are active as monomers, yet physiologically they also form homodimers and heterodimers during an immune reaction, hence eliciting a more pronounced immune response compared to a single chemokine (Paoletti et al., 2005; Kischer et al., 2009; Proudfoot and Uguccioni, 2016).

Functionally, chemokines can be classified into two main groups: the first is involved in the inflammation process while the second is involved in homeostatic cell migration. However, the biological functions of chemokines extend to many others such as controlling cell proliferation and differentiation, regulating angiogenesis, inflammatory responses, tumor growth and metastasis (Hughes and Nibbs, 2018). The various functions are dependent on the signaling pathways induced upon the binding of chemokines to their cognate receptors and are affected by several factors such as GAGs and the post-translational modifications of chemokines. GAGs play an important role in chemokine-chemokine and chemokine-receptor interactions (Salanga and Handel, 2011). Moreover, GAGs influence the immobilization of chemokines from the cell surface and extracellular matrix (ECM) which in turn affects the activity and distribution of chemokines post secretion (Salanga and Handel, 2011; Monneau et al., 2016). On the other hand, chemokines can undergo several post-translational modifications that impact their functions including citrullination (Proost et al., 2008), nitration/nitrosylation (Barker et al., 2017), cleavage by matrix metalloproteinases (MMPs), cathepsins, thrombin, plasmin, elastase, and the dipeptidyl peptidase CD26 (Van Lint and Libert, 2007; Metzemaekers et al., 2016). Moreover, the binding of chemokines to the ECM is affected by the proteolytic cleavage which aids several chemokines such as CCL21 (Schumann et al., 2010), CX₃CL1 (Hundhausen et al., 2003) and CXCL16 to detach from the ECM (Gough et al., 2004) to be released more readily allowing efficient GAGs binding. As a result, proteases help in modifying interstitial chemokine gradients regulating half-life and distribution (Barreira da Silva et al., 2015).

Chemokine receptors

Chemokine receptors can be classified as conventional (cCKRs) or atypical. To date, there are 22 chemokine receptors named based on the predominant type of chemokine to which they bind followed by R for “receptor” and a number annotating the receptor discovery (Murphy et al., 2000; Zlotnik and Yoshie, 2000; Stone et al., 2017). Accordingly, there are currently about 10 CCRs, 6 CXCRs, a single CX₃CR and XCR as well as 5 atypical receptors (Acr1, Acr2, Acr3, Acr4 and Acr5) (Hughes and Nibbs, 2018). A specific immune cell does not express fixed cCKRs and can undergo receptor switching that is crucial for altering the function based on the immunological response induced by a particular pathogen. For instance, antigen experienced B-lymphocytes upregulate CCR7 to direct activated B cells to T cell area (Reif et al., 2002), while CXCR4 and CXCR5 direct activated B cells to germinal centers (Allen et al., 2004), and CCR6 expression defines memory B cells (Suan et al., 2017).

Conventional receptors exist as homodimers and oligomers, yet they can also heterodimerize with atypical chemokine receptors, other cCKRs, or membrane proteins (Mellado et al., 2001; Chen et al., 2004; Wilson et al., 2005; Kumar et al., 2006; Sohy et al., 2009). Moreover, cCKRs are not only activated by chemokines. β -defensins, alarmin, high mobility group box 1 protein (HMGB1) and migration inhibitory factor (MIF) are among the non-chemokine ligands that can also activate cCKRs (Schiraldi et al., 2012; Tirone et al., 2018). Conversely, chemokines like CCL18 can bind to non-GPCR such as phosphatidylinositol transfer protein (PITPMN3) in the context of tumor cell invasion (Chen et al., 2011). Importantly, chemokines do not always activate a signal upon binding to their cognate receptors, but instead may act as natural antagonists (Nibbs et al., 2000; Loetscher et al., 2001; Petkovic et al., 2004).

On the other hand, atypical chemokine receptors are structurally related to cCKRs upon binding to chemokines with high affinity. However, they do not activate the same signaling pathways induced by cCKRs due to the absence or alteration of the intracellular signaling motifs (Bachelier et al., 2013; Nibbs and Graham, 2013). Functionally, atypical receptors control the localization, distribution and abundance of chemokines and hence, are considered efficient scavengers compared to cCKRs (Cardona et al., 2008). Accordingly, atypical receptors play an important role in controlling chemokines/cCKRs interactions by preventing unnecessary desensitization upon exposure to excess chemokines (Fukuma et al., 2003; Lee et al., 2003; Pruenster et al., 2009).

Chemokine families

The main function of the chemokine system is cell migration, especially leukocytes. Previously, chemokines were classified based on their function, whether inflammatory or homeostatic. However, the used nomenclature is based on their structural differences in their cysteine residues. For the past 3 decades, chemokine ligands and receptors were intensely reviewed in health (Hughes and Nibbs, 2018; Murphy, 2019; Schall and Proudfoot, 2011; Schall and Bacon, 1994; Zlotnik and Yoshie, 2012; Zimmerman et al., 2020; Capucetti et al., 2020; Sokol and Luster, 2015; Gustavsson, 2020) and disease (Rolin and Maghazachi, 2014a, 2014b; Aldinucci et al., 2020; Dhaiban et al., 2020; Elemam et al., 2020; Miyabe et al., 2019; Miao et al., 2020).

The CC chemokine family is composed of 28 ligands and 10 receptors in both human and mouse species. In this family, some receptors bind to multiple ligands while others are specific to one or two ligands only. For example, CCR1 binds CCL3, CCL4, CCL5, CCL7, CCL8, CCL13, CCL14, CCL15, CCL16 and CCL23. Similarly, CCR2 binds CCL2, CCL7, CCL8, CCL11, CCL13, and CCL16, while CCR3 binds various ligands including CCL5, CCL7, CCL11, CCL13, CCL15, CCL24, CCL26, and CCL28. Another inflammatory associated chemokine receptor CCR5, is known to bind CCL3, CCL4, CCL5, CCL7, CCL8, CCL14 and CCL16. CCR8 possesses the ability to bind CCL1, CCL8 and CCL18. On the other hand, CCR4 is known to bind CCL17 and CCL22, while CCR7 binds CCL19 or CCL21, and CCR10 binds CCL27 or CCL28. However, some CC receptors bind to only one ligand, as known with CCR6 binding CCL20, and CCR9 binding CCL25.

The second group of chemokines, CXC family, is composed of 6 conventional receptors and 16 ligands in human and mouse. Similar to the CC group, this family is composed of shared receptors that bind multiple ligands including CXCR1, CXCR2, and CXCR3. CXCR1 binds CXCL6 and CXCL8, while CXCR2 binds CXCL1-3, and CXCL5-8. Interferon regulated chemokines CXCL9, CXCL10, CXCL11 as well as CXCL4 bind CXCR3. The other receptors are more specific and bind to one ligand including CXCR4 which binds CXCL12, CXCR5 which binds CXCL13, and CXCR6 which binds to CXCL16. XC chemokine family is composed of one receptor (XCR1) and 2 ligands (XCR1 and XCR2) while the CX₃C family is composed of one receptor, that is CX₃CR1 which binds CX₃CL1.

The family of atypical receptors constitutes of 5 receptors: Acr1/DARC, Acr2/D6, Acr3/CXCR7, Acr4/CCRL1 and Acr5/CCRL2. These receptors bind to CC and CXC chemokine ligands, thus scavenging them and halting their effect on conventional chemokine receptors. The conventional and atypical chemokine receptors and ligands are illustrated and summarized in Fig. 1.

Chemokine signaling

Cell migration and adhesion are among the major biological responses occurring upon the binding of chemokines to their cognate receptors. Initially, chemokines tether to the extracellular loops leading to the entry of the N terminus to the heptahelical bundle,

Fig. 1 Conventional and atypical chemokines and chemokine receptors families. The upper panel shows the conventional chemokine receptors and their corresponding ligands including the CC chemokine family, CXC chemokine family, XC and CX₃C chemokine families. The lower panel shows the five different atypical receptors that play a role in scavenging certain ligands leading to the inhibition of conventional chemokine signaling. Chemokines are shown in colored circles.

thus inducing a conformational change (Kufareva et al., 2015; Kleist et al., 2016) that leads to activation of intracellular signaling pathways such as G α i, β -arrestins (Kehrl, 2006), or JAK-STAT (Bachelierie et al., 2013). The complexity of chemokine signaling is attributed to several reasons. First, the alternative splicing of transcripts encoding cCKRs not only alters the signaling pathways induced by a chemokine receptor, but also affects the ligand-binding specificity (Lasagni et al., 2003). Second, chemokines can bind to multiple cCKRs with different affinities. Accordingly, a chemokine receptor may have different ligands that induce different functions (Yu et al., 2000). For instance, CXCR3 binds CXCL11 with higher affinity compared to CXCL10 which results in skewing T cells toward Th1 by the former and toward Th2 by the latter (Zohar et al., 2014). This feature of promiscuity applies more to chemokines involved in inflammation as a robust mechanism against microbial infections. On the contrary, chemokines and cCKRs responsible for homeostatic cell migration tend to be more specific having a maximum of one or two ligands. For instance, CXCL12 binds CXCR4 which is responsible for myelopoiesis, B cell development, lymphopoiesis, differentiation and homing of hematopoietic stem cells and plasma cells in the bone marrow (Bachelierie et al., 2013). Another homeostatic chemokine is CXCL13, the ligand for CXCR5, which is a key regulator of leukocyte trafficking in secondary lymphoid organs (Bachelierie et al., 2013). In addition, the cell context where chemokines bind to their cCKRs is considered an important determinant of the induced signaling pathway (Steen et al., 2014). The signaling pathways induced upon binding of chemokines to their receptors contribute to many pathological diseases.

Chemokines in innate and adaptive immunity

The role of the chemokine system in immunity is a very wide topic given the vast roles it has on various innate and adaptive immune cells at different levels. The involvement of chemokines begins as soon as the immune cells reside in primary lymphoid organs and continue to control their localization in secondary and tertiary lymphoid organs as well as their homeostatic presence in the circulation. Further, chemokines and their respective receptors control the effector functions of distinct immune cells by influencing their migration and modulating their function within peripheral tissues. Moreover, chemokines play an important role in controlling memory cell function in lymph nodes (LNs) and in the periphery. In this section, we will try to summarize the most important roles of chemokines in innate and adaptive immunity aiming to illustrate how the redundant and non-redundant functions of the chemokine/chemokine receptor system contribute to fighting infections and malignancies.

Role in the innate immunity

Effects on monocytes and macrophages

Early during acute inflammation and in response to pattern recognition receptors (PRR) activation and cytokine stimulation, activated endothelium and immune cells release different chemokines to attract monocytes. Among these chemoattractant molecules, CCL2 and CCL7 are rapidly produced. CCL2 establishes a stable gradient for the migration of CCR2⁺ inflammatory monocytes into peripheral tissues by dimerizing and binding to extracellular matrix glycosaminoglycans (Kuziel et al., 1997; Proudfoot et al., 2003). Soluble CCL2 enters the draining LNs, providing access to monocytes. It can as well be detected in the serum during infection where it induces the migration of inflammatory monocytes from the bone marrow (Palframan et al., 2001; Shi and Pamer, 2011). Other chemokine receptors expressed on monocytes have distinct roles in adhesion and migration. These include CXCR2, CCR1, CCR5, CCR6 and CX3CR1 (Weber et al., 2001). The promiscuity of chemokine receptors allows CXCR2 to bind CXCL8 which induces a firm adhesion of monocytes to the vascular endothelium, while the binding of CXCR2 to the atypical ligand macrophage migration inhibitory factor (MIF) induces integrin-dependent chemotaxis of monocytes (Gerszten et al., 1999; Bernhagen et al., 2007). Although the role of CCL20/CCR6 axis in inducing monocyte migration in vitro is not well defined, experiments showed that CCR6 is necessary for inflammatory monocytes migration inside cutaneous tissues post immunization (Le Borgne et al., 2006; Shi and Pamer, 2011). Regarding the fractalkine receptor CX₃CR1, it is mainly expressed on anti-inflammatory or patrolling monocytes although it is also present but to a lesser degree on proinflammatory monocytes (Griffith et al., 2014). CX₃CR1 expressed on anti-inflammatory monocytes, promotes integrin-mediated adhesion within the vessel and provides pro-survival signals (Auffray et al., 2007; Landsman et al., 2009).

Effect on Dendritic Cells (DCs)

Dendritic cells are important initiators of the adaptive immune response. The release of CCL3, CCL4 and CCL20 during early pathogen encounter brings immature DCs into immediate contact with pathogen-associated molecular patterns (PAMPs) which bind to the various toll-like receptors (TLRs) expressed on DCs and allow their maturation (Banchereau and Steinman, 1998; Michelsen et al., 2001; Esche et al., 2005). CCR1, CCR2, CCR5, CCR6 and CXCR1 allow the recruitment of immature DCs to inflamed tissues while the expression of these receptors is reduced post activation (Caux et al., 2000; Sozzani et al., 2000). Mature DCs express CCR7 and follow a stable gradient of CCL21 and CCL19 (Dieu et al., 1998; Sozzani et al., 1998). CCL21 is produced by the lymphatic endothelium and released into the periphery where it binds GAGs (Sallusto et al., 1998; Weber et al., 2013). This mediates the entry of peripheral mature DCs to the draining LN (Tal et al., 2011). Furthermore, upon the entry of chemokine-rich interstitial fluid to the high endothelial venules (HEV) lumen, inflammatory monocytes are attracted via CCR2 and differentiate to monocytes-derived DCs which in turn play a crucial role in Th1 differentiation (Palframan et al., 2001; Shi and Pamer, 2011). The switch in chemokine receptor is essential for DCs migration into the lymphatics specifically to the T cell-rich regions of the LN where they act as professional antigen presenting cells and induce adaptive immune response.

Effects on neutrophils

Together with macrophages, neutrophils are among the earliest cells recruited to the sites of inflammation by chemokines such as CXCL8, CXCL5 and CXCL1, given these cells express CXCR1 and CXCR2 (Rot and von Andrian, 2004). Other chemokines attract neutrophils in an organ specific manner such as CCL3 and CCL4 which bind CCR1 (Lee et al., 2000). In addition to promoting directional motility and effector function, chemokines are vital during an infection for the persistent release of neutrophils from the bone marrow given they have a short life span of 6 h in the periphery. During infections, systemic increase of granulocyte-colony stimulating factor (G-CSF) induces the production of neutrophils and their release from the bone marrow by decreasing the production of CXCL12, increasing the release of CXCL2 and reducing CXCR4 expression on neutrophils (Kawakami et al., 1990; Semerad et al., 2002; Kim et al., 2006; Eash et al., 2010). The role of chemokines does not end at this stage and is further needed for neutrophils to migrate and gain access to areas of acute inflammation via rolling along the luminal surface of the endothelium where they bind CXCL1, CXCL2 or CXCL8. It is worth mentioning that the Duffy antigen receptor for chemokines (DARC/ACKR1) sequesters bound chemokine on the luminal surface of the endothelium and this immobilization of chemokines is important for binding immune cells, promoting their transmigration and regulating their entry in order to avoid undesired excessive inflammation (Proudfoot et al., 2003; Hillyer and Male, 2005; Pruenster et al., 2009). Other neutrophil chemo-attractants produced by macrophages and endothelial cells such as CCL3, CCL4, CCL5, CXCL1 and CXCL2 bind their respective receptors on neutrophils to enhance their entry into infected tissues, amplifying the immune response (Chou et al., 2010). Importantly, despite the redundancy in the action of chemokines in promoting and amplifying immune cell migration, different forms of the same chemokine can still exhibit distinct roles probably due to the differential binding capacity to a specific receptor (Griffith et al., 2014). For instance, monomeric CXCL8 dimers bind CXCR2 and induce initial neutrophil recruitment whereas the binding of the monomeric form to the same receptor is rather responsible for sustaining the recruitment (Das et al., 2010). Following their entry into the infection sites, neutrophils execute their phagocytic function, trapping pathogens in extruded DNA, and forming neutrophil extracellular traps (Griffith et al., 2014).

However, in order to ensure additional inflammatory cell influx, neutrophils continue to produce various inflammatory mediators based on the type of stimulus or immunological context. For instance, G-CSF induces the release of CXCL5 (Suzuki et al., 2002), and CXCL2 (Nguyen-Jackson et al., 2012). The Wntless-related integration (Wnt) signaling pathways trigger the release of CXCL8 and CCL2 (Jung et al., 2013) and organic dust triggers the release of CXCL8 and CCL3 (Blidberg et al., 2012).

Other chemokines released by neutrophils include CCL4, CCL5, CCL19, CCL20, CXCL1, CXCL9, CXCL10 and CXCL11 (Gasperini et al., 1999; Bennouna et al., 2003). These chemokines recruit additional neutrophils (CXCL1 and CXCL8), or other innate immune cells such as monocytes (CCL3 and CCL4), macrophages, DCs (CCL19, CCL20) and natural killer (NK) cells. Moreover, different subsets of T cells are also influenced by neutrophil chemokines. For instance, CXCL9 and CXCL10 harvested from IFN- γ plus lipopolysaccharide (LPS)- or TNF- α -treated neutrophils promoted the migration and the integrin-dependent adhesion of CXCR3-expressing Th1 cells (Gasperini et al., 1999). On the other hand, the release of CCL2 and CCL20 chemoattract Th17 cells, which plays important roles in adaptive immunity, as well as amplifies innate immunity by releasing CXCL8, CXCL1 and G-CSF to recruit additional neutrophils to the site of infection (Pelletier et al., 2010; Annunziato et al., 2015). This illustrates a clear and an important role of the chemokine system in linking the adaptive and innate arms of the immune system (Tecchio and Cassatella, 2016).

Natural killer cells

Two subsets of NK cells are found in the blood circulation characterized by the density of CD56 and CD16 markers on their surfaces. These are designated as CD56^{dim}CD16^{bright} and CD56^{bright}CD16^{dim} (Maghazachi, 2005). Earlier studies demonstrated that CXCL8 induced the in vitro chemokinesis of IL-2-activated NK cells (Sebok et al., 1993), whereas CCL2, CCL3, CCL4 and CCL5 induced the chemotaxis of these cells (Maghazachi et al., 1994). Other chemokines such as CXCL10 (Maghazachi et al., 1997; Taub et al., 1995), CXCL12 (Maghazachi, 1997), CCL1 (Inngjerdingen et al., 2000, 2001), CCL7, CCL8 (Allavena et al., 1994; Loetscher et al., 1996; Taub et al., 1995), CCL17 (Inngjerdingen et al., 2000), CCL19 (Al-Aoukaty et al., 1998; Kim et al., 1999), CCL20 (Al-Aoukaty et al., 1998), CCL21 (Kim et al., 1999), CCL22 (Godiska et al., 1997; Inngjerdingen et al., 2000), XCL1 (Bianchi et al., 1996; Hedrick et al., 1997; Maghazachi et al., 1997), and CX₃CL1 (Al-Aoukaty et al., 1998; Fraticelli et al., 2001; Imai et al., 1997), also promoted the in vitro chemotaxis of human NK cells. Inngjerdingen et al. (2001) reported the expression of messenger RNA for XCL1, CCR3, CCR4, and CCR5 in three different NK cell subsets. Those authors described in details the expression of chemokine receptors in these NK cell subsets. Berahovich et al. (2006) also demonstrated the expression of chemokine receptors and reported that human NK cells depending whether they were CD56^{bright} or CD56^{dim} variably express CXCR1, CXCR3, and CXCR4, and contain subsets expressing CCR1, CCR4, CCR5, CCR6, CCR7, CCR9, CXCR5, and CXCR6.

In addition, chemokines play positive roles in NK cell tissue localization (reviewed in Maghazachi, 2010). The main stimuli that regulate the expression of chemokine receptors which are involved in NK cell homing to normal or inflamed tissues, including tumors or organs such as the lungs and liver have been previously reviewed (Castriconi et al., 2018). CCL5 recruited NK cells corroborated with tumor regression, and abolished the anti-tumoral effects of immunotherapy (Bhat et al., 2020). In addition to chemotaxis, chemokines induced NK cell lysis of tumor target cells (Maghazachi et al., 1996). These observations clearly demonstrate that chemokines play vital roles in NK cell biology.

Effects on mast cells and eosinophils

Mast cells express a wide variety of PRRs and contain large granules of inflammatory molecules and hence, can immediately respond to acute inflammation. Moreover, degranulation of mast cells is considered an important source of chemokines required for neutrophil recruitment (Griffith et al., 2014). While responding to various stimuli, mast cells produce different chemokines including CCL2, CCL3, CCL4, CCL5, CCL11, CCL20, CXCL1, CXCL2, CXCL8, CXCL9, CXCL10, and CXCL11 (Marshall, 2004).

On the other hand, eosinophils respond to a wide variety of chemokines including CCL11, CCL24 and CCL26 upon binding to CCR1 and CCR3. These chemokine/chemokine receptors signaling pathways possess overlapping roles by promoting eosinophil migration to the peripheral tissues (Humbles et al., 2002; Mattes et al., 2002; Kalomenidis et al., 2005; Pope et al., 2005). In turn, when eosinophils are stimulated by thymic stromal lymphopoietin (TSLP), not only they exhibit increased adhesion by increasing their expression of ICAM-1 and CD18, but can also produce CCL2, CXCL1 and CXCL8 to further attract additional inflammatory cells (Wong et al., 2010). In this context, it is worth noting that tight regulation of chemokine effects in general is of high importance to prevent excessive and harmful inflammation. In vivo, CCL11 is cleaved and rendered inactive by a surface-associated protease, CD26 (Struyf et al., 1999).

Role in adaptive immunity

Effects on T lymphocytes

Different T cells express distinct chemokine receptors that define their functions. For instance, CCL1, CCL11, CCL17, CCL22, CCL24 and CCL26 selectively recruit Th2 lymphocytes which express CCR4, CCR8 and CCR3 (Mathew et al., 2001; Ono et al., 2003). During helminth infection and in response to B-cell derived CXCL13, Th2 and Tfh are induced upon CXCR5-mediated signaling in DCs and CD4⁺ T cells (León et al., 2012). Moreover, activated T follicular helper (Tfh) cells downregulate CCR7 and upregulate CXCR5, which allows their migration toward the follicle to instruct B cells in class switching (Schaerli et al., 2000; Kim et al., 2001b).

On the other hand, Th1 cells preferentially express CCR5, CXCR3 and CXCR6 and migrate in response to CCL3, CCL4, CCL5 or the ELR negative CXC chemokines (Luther and Cyster, 2001). Among the different chemokine receptors, CXCR3 plays a specific role in Th1 priming (Bromley et al., 2008; Groom et al., 2012). CXCL9 and CXCL10 produced in the draining LNs by mature DCs promote the migration of CD4⁺ T cells, leading to stable contacts with DCs which are necessary for optimal Th1 differentiation (Groom et al., 2012). In addition, this localization places Th1 in close proximity with IFN- γ producing cells such as CXCR3⁺ cells including NK, NKT, $\gamma\delta$ T, and innate-like CD8⁺ T lymphocytes (Bajénoff et al., 2006; Groom and Luster, 2011; Kastenmüller et al., 2012; Oghumu et al., 2013).

In response to viral infection and post antigen-specific activation, CD8⁺ T lymphocytes release large amounts of CCL3, CCL4 and CCL5 from their cytotoxic granules which recruit other inflammatory cells including phagocytes to amplify the immune response (Wagner et al., 1998). However, the optimal priming of CD8⁺ T cells requires their coordinated migration and interaction with DCs and CD4⁺ T cells which release CCR5 ligands that bind to CCR4 and CCR5 on CD8⁺ lymphocytes within the LN (Castellino et al., 2006). As developing immune memory is at the heart of adaptive immunity, it is important to highlight the chemokines involved in the function of central memory CD8⁺ T cells. Unlike naïve CD8⁺ T cells, the expression of CXCR3 on central memory T cells allows their preferential migration and localization within CXCL10 rich regions of the LNs where they interact with macrophages and DCs and rapidly produce IFN- γ . In response to IFN- γ , macrophages and stromal cells release CXCL9, directing other immune cells toward the sites of infection (Sung et al., 2012). In this context, CXCL9 and CXCL10 exhibit non-redundant roles in positioning central memory T cells to induce a rapid response during secondary infections.

When discussing the role of chemokines on lymphocytes, we ought to mention the role of T regulatory cells (Tregs) in regulating chemokine production in the LNs. The absence of Tregs causes an increase in the levels of chemokines and cytokines in the draining LNs which eventually retain the immune cells necessary to control viral replication instead of migrating toward infected tissues (Lund et al., 2008). Accordingly, Tregs have a critical function in controlling the levels of CCL3, CCL4 and CCL5 in order to restrict the priming of antigen-specific cells to high-avidity CD8⁺ T cells which establish protective memory (Pace et al., 2012). Moreover, B cell responses are also controlled by FoxP3⁺ Tregs which express CXCR5. This subset of T cells is controlled by the receptor programmed cell death protein-1 (PD-1) molecule which limits the numbers of Tfh and germinal center (GC) B cell numbers post immunization to reach optimal antigen-specificity (Linterman et al., 2011).

Effect on B lymphocytes

CXCR4 and CCR7 are required in attracting newly arriving B cell entry into the LNs (Okada et al., 2002). On the other hand, the expression of CXCR5 on mature B cells mediate their entry into the Peyer's patches, whereas the CXCR4/CXCL12 axis is rather important for the egress of B cells from the draining lymphatics (Schmidt et al., 2013). Post encountering antigens, B cells upregulate CCR7 while maintaining the expression of CXCR5 and this alteration of chemokine receptors guide B cells to get in contact with CD4⁺ Tfh cells (Reif et al., 2002; Okada et al., 2005; León et al., 2012). This interaction leads to a decrease in CCR7 receptor and the migration of B cells to germinal center where they undergo proliferation and hypermutation in multiple cycles via bidirectional migration between the dark and light zones of the germinal center mediated by switching the expression of CXCR4 and CXCR5 (Allen et al., 2004). Another important axis exhibiting potential role in the coordination and regulation of the humoral immune response is the CCL20/CCR6 where its disruption results in ineffective T-B cell conjugates and poor antibody quality (Lee and Körner, 2019). At present, CCR6 is the only known receptor for CCL20 (Baba et al., 1997). CCR6 is upregulated on B-cells after their activation in secondary lymphoid organs and it is also upregulated on Tfh cells and their precursors (Lee and Körner, 2019).

Role of chemokines in microbial infections

The role of the chemokines in health and disease and especially viral infections was previously reviewed in humans and mice (Melchjorsen et al., 2003; Raman et al., 2011). Additionally, serum levels of chemokines may be potential disease biomarkers as well as indicators of response to treatment. Chemokines are considered crucial in the antiviral response, as they enhance the innate and adaptive immune system to be cytolytic or to release antiviral mediators (Mahalingam et al., 2003). In order to escape this, viruses try to evade the immune system and bypass their effect by mimicking the host chemokine ligands and receptors (Fleming et al., 1999; Murphy, 2001). For example, respiratory syncytial virus (RSV) viral protein mimics the chemokine fractalkine CX₃CL1 and binds to its respective receptor CX₃CR1 (Tripp et al., 2001). Among the CC chemokines, CCL3 and CCL5 were highly associated with viral infections such as RSV and hepatitis C virus (HCV) (Harrison et al., 1999; Haeberle et al., 2001; Sung et al., 2001; Apolinario et al., 2002). This was further supported by CCL3^{-/-} mice that displayed a delay in viral clearance upon influenza virus, paramyxovirus, or cytomegalovirus (Cook et al., 1995; Domachowske et al., 2000; Salazar-Mather et al., 2000). CCL3 plays a detrimental role in infections, as CCL3-deficient mice displayed a lower inflammatory state in herpes simplex virus (HSV) and RSV infections (Tumpey et al., 1998; Haeberle et al., 2001). Likewise, CCR2^{-/-} mice had a decreased inflammatory reaction and increased viral titers in influenza virus infection (Dawson et al., 2000). On the other hand, RSV viral proteins were found to inhibit the expression of multiple chemokines such as CCL2, CCL3, CCL4 and CXCL9 in pulmonary leukocytes (Tripp et al., 2000). Other chemokines include CCL2 and CXCL10 were highly detected and associated with influenza infection (Dawson et al., 2000). CXCL10 along with CCL2 present in the cerebrospinal fluid (CSF) were identified to play a role in viral meningitis, promoting chemotaxis of immune cells (Lahrtz et al., 1997). Likewise, CCL2 was found to be one of the differentially expressed chemokine in HSV-1 encephalitis and is inversely correlated with the clinical status (Rösler et al., 1998). Also, it was found to be elevated in human immunodeficiency virus (HIV) infection and plays a role in promoting viral replication in T lymphocytes and macrophages (Fantuzzi et al., 2003; Campbell and Spector, 2008; Sabbatucci et al., 2015). CCL5 was associated with herpesvirus infections, as high levels were detected in murine and human herpesvirus infections, even in latent phases (Halford et al., 1996; Weinberg et al., 2002). CCL19 was found to be elevated at early and late time points of HIV infection, and is positively correlated with plasma HIV RNA levels (Damás et al., 2009; Fontaine et al., 2010). In contrast, its receptor CCR7 was downregulated in CD4⁺ T cells during HIV infection, thus promoting viral replication (Ramirez et al., 2014).

In viral infections, a cascade of events leads to the release of cytokines and chemokines that interact in order to establish viral clearance. For example, (IFN)- α/β were recognized as main inducers of CCL3 expression, which in turn, triggered recruitment of the

potent anti-viral NK cells (Salazar-Mather et al., 2000, 2002). Subsequently, NK cells released IFN- γ , which induced the expression of the interferon associated chemokines that promote the migration of T cells. These chemokines include CXCL9, CXCL10 and CXCL11, which bind CXCR3, that is highly affected in viral infections (Luster, 1998; Dawson et al., 2000; Haeblerle et al., 2001; Liu et al., 2001; Willemse et al., 2016). Reports have indicated the correlation between expression of CXCL9 in the liver with the viral activity of chronic hepatitis C (Apolinario et al., 2002). However, others indicated that CXCL9 and CXCL10 play a role in immune system overactivity and pathology such as that observed in hepatitis B virus (HBV) infection, where their neutralization led to a reduction in the severity of disease (Kakimi et al., 2001). CXCL10 was found to be elevated in the early stages of viral infections, as well as being positively associated with disease progression (Jiao et al., 2012). Moreover, CXCL10 was considered to be a prognostic factor upon antiretroviral therapy (Stylianou et al., 2000). CXCR3⁺ T cells are recruited through CXCL10 to HIV-infected lymph nodes, leading to the persistence of infection acquired immunodeficiency syndrome (Foley et al., 2005).

In HIV, the envelope glycoprotein (gp120) binds to CD4 on T cells along with a coreceptor binding via CXCR4 or CCR5, that are responsible for leukocyte signaling/chemotaxis and apoptosis (Deng et al., 1996; Dragic et al., 1996; Berger et al., 1999; Iyengar et al., 1999). On the other hand, the respective ligands CXCL12 and CCL5 were found to inhibit HIV infection (Cocchi et al., 1995; Bleul et al., 1996). Lack of CCR5 receptor is the natural resistance to HIV infection. This was first identified with the CCR5 delta32 (Δ 32) homozygous donor, where there is a 32-bp deletion in the CCR5 gene, thus producing a non-functional protein on T cells, which halts HIV entry. Upon transplantation of the bone marrow into the HIV patient, remission with undetectable viral load was achieved (Samson et al., 1996; Doms, 2000; Hütter et al., 2015). Trials were initiated where the CCR5 antagonists such as maraviroc and cenicriviroc showed great efficacy to block viral entry (Mehellou and De Clercq, 2010; Kim et al., 2016). On the other hand, viruses that utilizes CXCR were associated with worse clinical outcome (Connor et al., 1997). Hence, multiple non-peptide small-molecules and peptides that antagonize CXCR4 were investigated including AMD3100, AMD3465, AMD070 as well as isothioureas, indole, KRH, piperidine (Tamamura et al., 2006; Thoma et al., 2008; Mosley et al., 2009; Das et al., 2015; Wu et al., 2015). The role of chemokines in HIV infection was previously reviewed (Maghazachi and Al-Aoukaty, 1998).

Similar to HIV infection, CCR1, CCR2, CCR5 and CXCR3 are known to contribute to the pathogenesis of HCV infection (Wald et al., 2007; Larrubia et al., 2008). CCR1 and CCR5 were differentially expressed in the peripheral blood and intrahepatic T cells from HCV patients, especially CD8⁺ T cells showing a cytotoxic phenotype (Lichterfeld et al., 2002; Ahlenstiel et al., 2004). CCL5 binds CCR1 or CCR5 receptor and play a critical role in HCV infection (Fahey et al., 2014). The virus possesses the ability to affect CCL5 expression and secretion by T cells via interferon regulatory factors and the NF- κ B signaling pathway (Nattermann et al., 2006; Katsounas et al., 2012). CCR2 and its ligand CCL2 were increased in the HCV patients, and showed a correlation with the liver inflammation state as well as progression to cirrhosis (Asselah et al., 2005; Neuman et al., 2007; Farci et al., 2012). CXCR3 ligands such as CXCL10 and CXCL11 are enhanced in HCV infection by the presence of Th1-type cytokines IFN- γ and TNF- α in the liver (Helbig et al., 2009). Another vital chemokine is CXCL16, which was reported to induce the recruitment of CXCR6⁺ lymphocytes such as inflammatory Th1 and Th17 cells, leading to excessive tissue damage (Kim et al., 2001a; Oo et al., 2010; Guidotti and Iannacone, 2013).

Chemokines connect several members of the innate and adaptive immune system in viral infections. For example, in HCV infection, resident Kupffer cells in the liver secrete CCL2 stimulating the recruitment of CCR2⁺ DCs and CD8⁺ T cells (Boisvert et al., 2003; Decalf et al., 2007). This leads to the secretion of proinflammatory cytokines and chemokines such as TNF- α , CXCL10 and CCL4 that attract NK cells and promote IFN- γ production. Subsequently, macrophage activation occurs followed by production of other chemokines such as CCL3 and CXCL9 that would recruit CD4⁺ T cells (Simpson et al., 2002; Salazar-Mather and Hokeness, 2006; Heydtmann, 2009). Other players of inflammation in viral infection are neutrophils that secrete CXCL8 (Wisniewska-Ligier et al., 2006). CXCL8 causes the migration of neutrophils through CXCR1 and CXCR2 to the liver leading to further exacerbation of the inflammation (Polyak et al., 2001; Neuman et al., 2007). In HCV infection, CXCL8 production is a downstream effect of the binding of viral proteins to TLR2, TLR3, and TLR7 and activation of the NF- κ B pathway (Szabo et al., 2007; Wagoner et al., 2007). On the other hand, CXCL8 and CCL5 levels were elevated in the nasal lavages of RSV patients (Noah et al., 1995; Sheeran et al., 1999). Similar to lymphocyte choriomeningitis virus, West Nile virus, RSV, and HCV infections (Asensio and Campbell, 1997; John et al., 2003; Nischalke et al., 2004; Shirato et al., 2004), high expression levels of CCL2, CCL3, CCL5, and CXCL10 were found in avian influenza virus infections, and even much higher than in human influenza infection (Zhou et al., 2006). Upon CCL5/CCR5 axis engagement and activation, it was found that prevention of apoptosis of influenza virus-infected macrophages takes place, permitting viral persistence (Tyner et al., 2005).

In bacterial infections, CCL4 was elevated while CXCL8 expression was unchanged. Also, CCL2 was high in bacterial infections and even higher than in viral infections (Holub et al., 2013). Sepsis, community-acquired pneumonia, and skin abscess bacterial infections displayed high levels of CCL5, while CXCL10 was elevated in septic cases. This indicates that this chemokine contributes to the pathogenesis of bacterial infections (Cavalcanti et al., 2016). Levels of CCL2, CXCL1, CXCL8, CXCL9, and CXCL10, were found to be higher in infants with suspected late-onset infection, with CXCL10 as a sensitive early marker of infection (Ng et al., 2007). Interestingly, a study by Liu et al. reported CXCL8 to be higher in patients with bacterial infection more than those with viral infections, as well as showing a differential expression between gram negative and gram-positive bacteria. On the other hand, CXCL10 showed an opposite pattern with higher expression in the virally infected patients (Liu et al., 2016).

Regarding the parasitic infections, chemokines are involved in *Plasmodium* infection, where CCL2 induces the recruitment of CCR2⁺ cells to the site of infection (Belyaev et al., 2013). Also, parasite antigens and tissue damage caused by *Schistosoma* cercariae were found to be the cause of production of CXCL1, CXCL2 and CXCL8, thus inducing the migration of neutrophils and antigen presenting cells to the skin (Mountford and Trottein, 2004; McGovern and Wilson, 2013). CCL5 was reported to play a critical role

in B cell proliferation in *Trypanosoma cruzi* infection (Sullivan et al., 2011). Furthermore, CCL5 along with CXCL9 and CXCL10 were highly elevated in parasitic infections as they aid in controlling these infections (Talvani et al., 2000). Similar to viruses, parasites try to mimic the chemokine system and bind to chemokine receptors, thus enhancing cell migration of specific immune cells (Stein et al., 2009).

Conclusions

Chemokines is a large group of soluble ligands that bind to respective receptors that belong to GPCRs family. They have fundamental roles in the homeostasis, survival and migration of the immune system, including the innate (macrophages, neutrophils, DCs, NK cells) and adaptive (B and T cells) arms. Furthermore, they are involved in several physiological processes such as cell proliferation, survival, angiogenesis and differentiation, as well as pathological diseases like inflammation, autoimmunity, cancer growth, and microbial infections (viral, bacterial and parasitic). In infections, chemokines promote the migration of immune cells to the infection site in order to stimulate pathogen elimination. However, excessive stimulation and secretion of certain chemokines could cause more damage, excessive inflammation and disease progression.

Introduction

Immune tolerance is an essential process in the immune system that prevents T cells and B cells from auto-reactive generation, and it is an important topic in auto-immunity, cancer, organ transplantation, and infectious diseases.

B cells have two types of immune tolerance, including central tolerance in the bone marrow and peripheral tolerance in peripheral tissues. If immature B cells respond to bone marrow cells' auto-antigens with high avidity in central tolerance, they will undergo receptor editing by somatic recombination or clonal deletion via apoptosis. If immature B cells react to self-antigens with low avidity in central tolerance, they will undergo anergy. Anergy is a state in which immune cells would be unresponsiveness in terms of function. Apropos B cells peripheral tolerance, If mature B cells interact with self-antigens, they will experience anergy or deletion. Sometimes, self-antigens can provoke inhibitory receptors such as CD22, CD32b on mature B cells, contributing to inhibiting B cells (Singh and Schwartz, 2006). It is noteworthy that Cbl-b plays an important role in anergy (Jeon et al., 2004).

During the T cells' development in the thymus and central tolerance, auto-reactive immature T cells are purged by negative selection via apoptosis. This event happens when T cells recognize self-peptides in the context of thymic epithelial cells' MHC with high affinity. Recognition of self-peptides in the context of thymic epithelial cells' MHC with low affinity—also known as positive selection—leads to generating the single positive T cells, including CD4⁺/CD8⁻ or CD4⁻/8⁺ T cell. Death by neglect is a phenomenon in the thymus cortex in which double-positive (CD4⁺/CD8⁺) immature T cells do not recognize the peptide-MHC complex, and they are undergone apoptosis. Autoimmune regulator (AIRE) has a vital role in T cell central tolerance. AIRE mutations cause autoimmune polyendocrine syndrome type 1 (APS1), also called autoimmune polyendocrinopathy-candidiasis-ectodermal

dystrophy (APECED). Increased susceptibility to candidiasis is an APECED-related symptom. AIRE acts as a tissue-restricted antigens (TRAs) expression regulator in the medullary thymic epithelial cell, where it orchestrates self-antigens presentation to autoreactive T cells to negative selection (Singh and Schwartz, 2006).

T cell-related peripheral tolerance includes anergy by lacking co-stimulator such as B7 molecule, suppression by Treg cells, and deletion via apoptosis (Singh and Schwartz, 2006).

Immune tolerance in cancer

The failure of immune surveillance has been understood in tumor progression. One of the causes of this progression is the induced immune tolerance in the tumor microenvironment (TME). Generally, the involving factors in cancer immune tolerance include host T cell direct deletion, direct tolerization by tumor cells, Treg cell-mediated immunity suppression, tumor ignorance, and tumor antigens cross-presentation-induced T cell tolerization (Mapara and Sykes, 2004). Here, we will expatiate involving elements in inducing immune tolerance in the TME.

Myeloid-derived suppressor cells

Myeloid-derived suppressor cells (MDSCs) are a heterogeneous population of cells from the immature myeloid lineage. These cells' expansion in the TME leads to suppressing T-cell responses. MDSCs are comprising myeloid progenitor cells and immature macrophages, immature granulocytes, and immature dendritic cells. MDSCs two main subsets are including monocytic MDSCs, which have a CD11b⁺ LY6G[−] LY6C^{hi} phenotype, and granulocytic MDSCs, which have a CD11b⁺ LY6G⁺ LY6C^{low} phenotype. MDSC suppressive activity mechanisms include Arginase 1 and inducible nitric oxide synthase (iNOS), L-cysteine degradation, reactive oxygen species (ROS), peroxynitrite (ONOO[−]), production of prostaglandin E2 (PGE₂), and T_{reg} cell induction (Gabrilovich and Nagaraj, 2009; Veglia et al., 2018). We are going to expatiate these mechanisms below.

iNOS, arginase, and L-cysteine degradation

iNOS, which generates nitric oxide (NO), has been upregulated by STAT1 in monocytic MDSCs (Movahedi et al., 2008). NO suppresses T cell activation via Jak3 and STAT5 inhibition (Bingisser et al., 1998), inhibition of MHC-II transcription (Harari and Liao, 2004), and induction of T cell apoptosis (Vig et al., 2004; Rivoltini et al., 2002). Also, NO contribute to promoting metastasis via vascular endothelial growth factor-C (VEGF-C) production in vitro (Nakamura et al., 2006). NO inhibition with radiotherapy leads to promote anti-tumor responses (Xu et al., 2020). iNOS and arginase 1 (which catalyze L-arginine to urea and L-ornithine) use L-arginine as a substrate. Arginase 1 overexpression has been indicated on MDSCs infiltrating tumors, which destroys L-arginine non-essential amino acid from the TME (Rodriguez et al., 2005; Ochoa et al., 2007). Consequently, L-arginine deficiency accounts for the downregulated CD3 ζ -chain expression (Rodriguez et al., 2002), impaired the expression of cyclin D3 and cyclin-dependent kinase 4 (cdk4) (Rodriguez et al., 2007), arrested T cell proliferation (Rodriguez et al., 2010). MDSCs can degrade L-cysteine amino acid and L-cystine, consequently inhibiting T cell activation and function (Srivastava et al., 2010).

Reactive oxygen species

ROS serve as an essential factor for MDSC suppressive activity in cancer (Kusmartsev et al., 2004; Schmielau and Finn, 2001; Kusmartsev et al., 2005; Mantovani et al., 2003). H₂O₂, which formed from MDSC-derived superoxide anion (O₂[−]), affects T cells, including reduced CD3 ζ -chain expression (Schmielau and Finn, 2001), decreased cytokine production (Schmielau and Finn, 2001), and downregulated IFN- γ expression (Corzo et al., 2009). NADPH oxidase (NOX2) mediates increased ROS production in MDSCs in patients with head and neck cancer (Corzo et al., 2009). It has revealed that integrins on MDSCs such as CD11b, CD18, and CD29 interact with T cells, contributing to increased ROS formation and suppression of CD8⁺ T cell responses (Kusmartsev et al., 2004).

Peroxynitrite. The reaction between NO and O₂[−] products ONOO[−]. Tumor progression has been associated with high peroxynitrite levels in many cancer types (Nakamura et al., 2006; Cobbs et al., 2003; Bentz et al., 2000; Dairou et al., 2005; Ekmekcioglu et al., 2000; Kinnula et al., 2004). A study has found that MDSCs induce immune tolerance in antigen-specific CD8⁺ T cells in cancer via nitrosylation of tyrosines within the TCR/CD8 complex (Nagaraj et al., 2007). In this situation, T cells are unresponsiveness. ROS and peroxynitrite overexpression during direct cell-cell contact incites nitration of TCR/CD8 (Nagaraj et al., 2007). Furthermore, peroxynitrite plays a role in the nitrosylation of CCL2 chemokine. CCL2-CCR2 axis has a pivotal role in MDSCs infiltration into the TME (Huang et al., 2007). Besides, CCL2 mediates MDSCs recruitment in cancer, contributing to colorectal carcinogenesis (Chun et al., 2015). Nitrosylation of CCL2 in the cancer environment prevents cytotoxic T lymphocyte trafficking to the tumor, promoting cancer development and immune tolerance (Molon et al., 2011).

Production of PGE₂

PGE₂ is one of the prominent factors to promote an immune tolerance state in favor of tumor progression. PGE₂ incites suppressive function of MDSCs, contributing to tumor progression (Sinha et al., 2007a; Tomić et al., 2019). In prostate cancer, obesity leads to recruit macrophages into the TME and induces tumor-associated macrophages (TAMs) polarization via PGE₂/COX-2 pathway. Besides, obesity increases CCL2, PGE₂, and COX-2 expression in prostate cancer cells (Galván et al., 2017). PGE₂ reduced MDSCs'

capacity to produce proinflammatory cytokines and raised their ability to produce IL-27, IL-33, and TGF- β (Tomić et al., 2019). Recently, a paper has reported that the P50 NF- κ B-dependant differentiation of MDSCs has been mediated by tumor-derived PGE₂ (Porta et al., 2020). It has been indicated that sulforaphane drug inhibits PGE₂ synthesis in breast cancer cells via NF-E2-related factor 2 (Nrf2) and prevents to accumulation MDSCs (Rong et al., 2020). Epigenetics processes have regulated MDSCs tolerogenic functions. In this context, a study revealed PGE2-mediated upregulated DNA methyltransferase 3A (DNMT3A) in MDSCs that DNMT3A amplifies MDSC-suppressive properties (Rodríguez-Ubreva et al., 2017).

Treg cell induction and cell anergy

MDSCs can induce the development of forkhead box protein P3⁺ (Foxp3⁺) T_{reg} in vivo (Huang et al., 2006; Yang et al., 2006a). In A20 B-cell lymphoma model, It has been identified that T_{reg} induction by MDSCs is dependant on arginase but is TGF- β independent (Serafini et al., 2008). On the contrary, another study reported that MDSCs suppress iT_{reg} differentiation from naive CD4⁺ cells and require ROS and indoleamine 2,3-dioxygenase (IDO) but do not require arginase 1, iNOS, NO, cystine/cysteine depletion, PD-1, and PD-L1 signaling, or COX-2 independent (Centuori et al., 2012). A cancer immune tolerance in breast cancer can be induced by MDSCs-expressing IDO, increasing T_{reg} cell expansion (Li et al., 2018). Inducing anergy in NK cells can be incited by MDSCs via membrane-bound TGF- β , STAT5 activity, ARG-1, or as well as the NKp30 receptor (Li et al., 2009; Liu et al., 2007; Hoechst et al., 2009; Oberlies et al., 2009). In glioma, NKG2D and IFN- γ production can also be inhibited by MDSCs (Alizadeh et al., 2010). MDSCs can expand and differentiate T_{reg} in the tumor-bearing host by IL-10 and TGF- β upregulation (Huang et al., 2006). Using tumor mouse models, It has demonstrated that MDSCs can differentiate macrophages into M₂ phenotype by producing IL-10 and decreasing macrophage production of IL-12 (Kerkar et al., 2011; Sinha et al., 2007b).

Regulatory T cells

First, T_{reg} participation in anti-tumor immunity has been introduced by two studies (Onizuka et al., 1999; Shimizu et al., 1999). A growing body of evidence has indicated that T_{reg} cells are increased and infiltrated into many types of tumor, including head and neck (Schaefer et al., 2005), breast (Liyanage et al., 2002), lung (Wolf et al., 2003), liver (Ormandy et al., 2005), gastrointestinal tract (Ichihara et al., 2003; Sasada et al., 2003), pancreas (Hiraoka et al., 2006), prostate (Watanabe et al., 2019), ovary (Curiel et al., 2004; Sato et al., 2005), brain (El and Lesniak, 2006), kidney (Giraldo et al., 2017), and B cell non-Hodgkin-lymphoma (Yang et al., 2006b). Significantly, there is a negative correlation between the high frequency of tumor-infiltrating Foxp3⁺ cells and patients' survival in solid tumors, including cervix, kidney, breast, lung, and melanomas (Shang et al., 2015; Shou et al., 2016; Tao et al., 2012). There are discrepancies in other studies. Two studies have reported the high frequency of tumor-infiltrating Foxp3⁺ cells associated with improved colorectal cancer survival (Salama et al., 2009; Frey et al., 2010). High ratios of Foxp3⁺ T_{reg} cells to tumor-infiltrating CD8⁺ T cells have been associated with patients' poor prognosis. It has been seen in patients with breast (Bates et al., 2006), gastric (Sasada et al., 2003), and ovarian cancer (Curiel et al., 2004; Sato et al., 2005). T_{reg} can inhibit high endothelial venules neogenesis via inhibition of T-cell activation's self-amplifying loop, which causes decreased lymphocyte infiltration and development of the tumor tissue (Colbeck et al., 2017; Hindley et al., 2012).

Here, we are going to highlight the suppressive mechanisms of Treg cells. Treg cells constitutively express IL-2 receptor subunit- α or CD25, which causes to deplete of IL-2 from surroundings; thus, effector T cell functions are reduced (Chinen et al., 2016). T_{reg} cell releases IL-10, TGF- β , and IL-35 to inhibit effector T cells (Collison et al., 2007; Taylor et al., 2006). Treg cells derived from the TME can also induce apoptosis in NK and CD8⁺ T cells via granzyme B, perforin, and Fas/Fas-L interaction (Cao et al., 2007; Strauss et al., 2009; Ohue and Nishikawa, 2019). IDO is an enzyme in tryptophan (Trp) metabolism which degrades Trp to kynurenine in TME, and Trp starvation results in T cell dysfunction (Uyttenhove et al., 2003). IDO secretion is mediated by the interaction between CTLA-4 on T_{reg} cells and B7 on APCs (Mellor and Munn, 2004). Adenosine metabolism has been seen in T_{reg} cells. Oxidative stress causes T_{reg} cells apoptosis, contributing to the release of ATP from them. CD39 and CD73 molecules are expressed considerably by T_{reg} cells, and these molecules orchestrate metabolism ATP to adenosine. Binding adenosine to the A2A receptor (A2AR) inhibits effector T cells (Maj et al., 2017). Another Treg cell inhibitory mechanism in TME is immune checkpoint involvement. These immune checkpoints are including lymphocyte activation gene-3 (LAG-3) (Camisaschi et al., 2010), PD-1 (Kumar et al., 2017), CTLA-4 (Matoba et al., 2019), T-cell immunoglobulin mucin (TIM-3) (Liu et al., 2018), TIGIT (Kurtulus et al., 2015), and inducible T-cell costimulatory (ICOS) (Li and Xiong, 2020). T_{reg} cells inhibit DC maturation and antigen presentation via CTLA4-B7 interaction (Ohue and Nishikawa, 2019).

Tumor-associated macrophages

TAMs have different roles in tumor progression and cancer immune evasion. TAMs also play an essential role in angiogenesis, migration, invasion, metastasis, and epithelial-mesenchymal transition (EMT) (Aras and Zaidi, 2017). TAMs suppress tumor immunity via mediators production, including IL-10, TGF- β , Arginase-1, IDO 1/2, and prostaglandins (Aras and Zaidi, 2017; Mantovani et al., 2017). Hypoxia and HIF-1 α upregulate PD-L1 expression on TAMs, inhibiting effector T cell via interaction with PD1 (Doedens et al., 2010). In squamous cell carcinoma, TAMs phenotype polarization has been mediated by cancer-associated fibroblasts (CAFs) via IL-10, TGF- β , and arginase-1 release (Takahashi et al., 2017). In bladder cancer, DC-SIGN⁺ TAMs infiltration into the TME is associated with promoting tumor immunity tolerance (Hu et al., 2020). In breast cancer, progranulin (multi-functional growth factor) mediates PD-L1 expression on TAMs via the STAT-3 signaling pathway, promoting breast tumor immune

escape (Fang et al., 2021). In breast cancer and ovarian cancer, the lncRNA-Xist/miR-101-3p/KLF6/C/EBP α axis causes TAMs polarization (Zhao et al., 2021). TAMs express immune checkpoints such as PD-L1, PD-L2, B7-H4, and VISTA, which trigger inhibitory signals to effector T cells (Mantovani et al., 2017).

T helper 2 (Th2)-mediated immunity

Th₂-mediated immunity plays a role in the inhibition of anti-tumor immunity. Type 2 cytokines such as IL-4 and IL-13 induce a tolerogenic state in TME, contributing to tumor development. However, Th₂-mediated immunity acts as a double-edged sword. Indeed, studies have revealed that Th₂ and its cytokines also harm tumor growth. For example, IL-13 has reduced tumorigenicity in fibrosarcoma tumor models and B16F1 melanoma (Ma et al., 2004).

Several studies have shown positive effects of Th₂-mediated immunity on tumor progression. IL-13, IL-4R, STAT6 caused to reduce tumor immunosurveillance (Terabe et al., 2000). It has been reported that lacking B cells have been associated with enhanced anti-tumor responses (Shah et al., 2005; Tadmor et al., 2011). In a study, IL-4 exerted a negative effect on tumor clearance, and it interrupted tumor-induced CD8⁺ T-cell responses (Olver et al., 2006).

T helper 17

Th17 cell has contrasting dual roles in cancer immunity in terms of anti-tumoral and pro-tumoral (Dahal, 2017). Here, we emphasize its pro-tumoral role.

IL17A-producing Th17 can promote lung cancer metastasis in murine models (Kulig et al., 2016). Tosolini et al. (2011) have confirmed a relationship between poor prognosis and high expression of the Th17 in patients with colorectal cancer samples. In the tumor's animal model, IL-17 facilitated MDSCs activation, MDSCs accumulation, and decreased CD8⁺ T cells infiltration (He et al., 2010), suggesting Th17 cells may suppress anti-tumor immunity.

Exhausted T cells and NK cells

In chronic infections and cancer, T cells are affected by persistent antigens and inflammatory signals. This condition is usually related to T cell dysfunction that has been termed exhaustion. Exhausted T cells lose their powerful effector functions, express multiple inhibitory receptors such as PD-1, TIM-3, LAG-3, and become exhausted, causing induce immune tolerance. T cell exhaustion is usually related to ineffective control of tumors, but repairing exhausted T cells can restore immunity (Wherry and Kurachi, 2015). Immune-suppressive factors in the tumor microenvironment such as IL-10, TGF- β , NOS, IDO, and hypoxia can induce exhaustion phenotype in tumor-specific T cells (Schietinger and Greenberg, 2014). In turn, These cells suppress anti-tumor-specific responses.

Although NK cells have possible cytolytic activity against tumors or infected cells, NK cells show impaired effector functions in hosts suffering from tumors or chronic infections (Bi and Tian, 2017).

Taken together, it has been concluded that exhausted cells have been invigorated by TME elements and these cells incite an excess tolerogenic state in TME.

Immune checkpoints

Inhibitory immune checkpoints are molecules that transduce negative signals to the immune cell. Blocked of these molecules is a novel way in cancer immunotherapy. The ligands of immune checkpoints have been expressed on tumor cells, causing anti-tumor immunity tolerance via interaction with immune checkpoints on the immune cell in TME. Inhibitory immune checkpoints are including CTLA-4, PD-1, T cell membrane protein 3 (TIM-3), lymphocyte activation gene 3 (LAG-3), T cell immunoreceptor with Ig and ITIM domains (TIGIT), B and T lymphocyte attenuator (BTLA), adenosine A2a receptor (A2aR), and killer cell immunoglobulin-like receptor (KIR) (Pardoll, 2012; Anderson et al., 2016). Besides, several novel immune checkpoints have introduced in recent years, including V-domain Ig suppressor of T cell activation (VISTA) (Gao et al., 2017), ST2 (Van der Jeught et al., 2020), CD47 (Logtenberg et al., 2019), Siglec (Fudaba et al., 2021), annexin A5 (Kang et al., 2020), CD200 (Xiong et al., 2020), SLAMF6 (Yigit et al., 2019), and CD39/CD73 (Moesta et al., 2020).

Immune checkpoints expression in TME can be affected by epigenetic mechanisms, contributing to inducing immune tolerance. Several studies have shown that DNA hypomethylation on H3K9me3 and H3K27me3 in colon and breast TME leads to expressing the immune checkpoints, including CTLA-4, PD-1, TIM-3 LAG-3 in transcription level (Sasidharan Nair et al., 2018a,b; Elashi et al., 2019).

MicroRNAs (miRNAs) and long non-coding RNAs (lncRNAs) can also regulate immune checkpoints expression in cancer. In lung cancer, p53/miR-34/PD-L1 axis mediated tumor immune evasion (Cortez et al., 2016). In contrast, miRNA-424(322) downregulated PD-L1 expression in human cancer cell lines (Xu et al., 2016). In nasopharyngeal carcinoma, co-expression PD1 and AFAP1-AS1 as a lncRNA have associated with poor prognosis (Tang et al., 2017).

Tolerogenic dendritic cells

Derivative factors of tumor which induce tolerogenic DCs include PGE2, TGF- β , Wnt signaling, HMGB1, CXCL12, GCSF, CCL2, VEGF, tumor-derived Exosomes delivering arginase-1 and mir-212-3p (DeVito et al., 2019). It has been reported that the CD31 molecule incites DCs polarization toward tolerogenic DCs (Clement et al., 2014). Tolerogenic DCs' inhibitory mechanisms include IDO expression, TGF- β , IL-10 secretion, Fas-L expression, PD-L1/PD-L2 expression, ILT3/4 up-regulation, and TRAIL interaction with TRAIL receptor (Fucikova et al., 2019; Brenk et al., 2009; Izawa et al., 2012). By contrast, activational receptors and functions have been downregulated in these cells, including CD40, CD80, CD86, TNF- α , IL-12, IL-6, and NF- κ B (Fucikova et al., 2019). In the animal models, DCs promote Treg cells' induction via TGF- β signaling, orchestrated by tumor cells (Ghiringhelli et al., 2005). In breast cancer, DCs incite CD4⁺ T cells to IL-13 secretion, contributing to tumor development (Aspord et al., 2007). It has been identified that M2 macrophages and tolerogenic DCs express MerTK molecule, which is a family of tyrosine kinase receptors (TAM-R). Besides, mononuclear cells-infiltrating human breast cancer tumors such as activated B lymphocytes and regulatory T cells and CD4⁺ and CD8⁺ T cells express MerTK. Gas6 and PROS1 are the ligands of TAM-R. Notably, IL-10 production is regulated by MerTK/PROS1 axis in tolerogenic DCs, promoting immunosuppressive TME (Giroud et al., 2020).

Regulatory B cells

Several B_{regs} phenotypes have been known in human cancers, including B10 B_{reg}, granzyme B (GrB⁺) B_{reg}, TIM-1⁺ B_{reg}, PD-1^{hi} B_{reg}, and PD-L1⁺ B_{reg} (Guan et al., 2016; Hu et al., 2019; Ye et al., 2018; Xiao et al., 2016; Wu et al., 2020a). Cross-talk between regulatory B cells (B_{regs}) and TME components has revealed that B_{regs} account for tumor progression. The mechanisms that B_{regs} impede anti-tumor immunity in TME are including immunosuppressive cytokine production such as IL-10, TGF- β , and IL-35, the expression of inhibitory molecules such as PD-1, PD-L1, and Fas-L, and provoking MDSCs (Shang et al., 2020). Glioma-derived ADAM10 and placental growth factor can provoke B_{reg} cells differentiation (Ye et al., 2014; Han et al., 2014). Consequently, tumor-specific CD8⁺ T cells are suppressed. In patients with lung cancer, peripheral Breg cells' frequency has increased compared to healthy individuals (Zhou et al., 2014). In gastric cancer, CD19⁺CD24^{hi}CD38^{hi} B_{reg} cells play a crucial role in suppressing tumor immunity via the inhibition of IFN- γ and TNF- α secretion and the up-regulation of the T_{reg} cells mediated by TGF- β 1 (Wang et al., 2015). IL-35 production from CD1d^{hi}CD5⁺B cells stimulates a protumorigenic state in pancreatic cancer (Pylayeva-Gupta et al., 2016).

Immunosuppressive cytokines

Immunosuppressive cytokines are including TGF- β , IL-10, and IL-35. In melanoma, MDSCs can inhibit T cells by producing TGF- β (Filipazzi et al., 2007). We have discussed apropos to the immunosuppressive cytokines in previous sections.

Immunosuppressive metabolites

Several critical immunosuppressive metabolites in TME and cancer metabolism induce immunotherapy resistance and tumor immunity tolerance. These metabolites include adenosine, R-2-hydroxyglutarate, glutamine, and methylglyoxal (Jiang et al., 2020).

We earlier discussed adenosine. In NK cells, adenosine can incite an immune tolerance state via decreasing the production of IFN- γ and TNF- α . Besides, adenosine reduced the proliferation and differentiation ability of NK cells (Beavis et al., 2013; Raskovalova et al., 2006). Adenosine/A2AR axis in macrophages leads to M2 macrophages phenotype polarization via down-regulating IL-2, TNF α , and NO expression and upregulating arginase-1, IL-10, and VEGF (Jiang et al., 2020; Ramanathan et al., 2007). Adenosine facilitated CD11b⁺ Gr1⁺ MDSCs expansion and their immunosuppressive activity (Ryzhov et al., 2011).

One of the important oncometabolites is R-2-hydroxyglutarate that release into the TME by glioma tumor cells, catalyzed by isocitrate dehydrogenase (IDH) mutations. R-2-hydroxyglutarate is taken up by T cells; consequently, NFAT activation, polyamines biosynthesis, T cell proliferation, and function are inhibited (Bunse et al., 2018).

One of the essential factors for cancer growth is glutamine. Glutamine induced a tolerogenic state in effector T cells tumor-bearing mice. Using glutamine antagonism named JHU083 reduced hypoxia and acidosis, increasing effector T cells activation and anti-cancer immunity (Leone et al., 2019). JHU083 inhibited tumor growth, MDSCs recruitment, expansion, and IDO/kynurenine expression; in turn, it increased MDSC to M1 macrophage conversion, tumor sensitivity, and immunotherapy and MDSC apoptosis (Oh et al., 2020). It is noteworthy that glutamine metabolism is essential for CD8⁺ T cells differentiation and function (Sinclair et al., 2013).

The role of methylglyoxal in tumor malignancy has been proven (Antognelli et al., 2019; Nokin et al., 2019). Methylglyoxal is a side biochemical product arising from aerobic glycolysis (Nokin et al., 2019). MDSCs attenuated CD8⁺ T cells via dicarbonyl radical methylglyoxal accumulation. In murine cancer models, methylglyoxal blockade hindered T cell suppression mediated by MDSCs, resulting in tumor immunotherapy improvement (Baumann et al., 2020).

Immune tolerance in autoimmunity

Robust immune response to self-antigens leads to the incidence of the broad spectrum of autoimmune maladies. Here, we will expatiate the immunoregulatory molecules involving immune tolerance, which their deficiencies cause autoimmunity.

B cell and T cell tolerance

B cells and T cells are central elements of adaptive immunity that can distinguish self-antigens from non-self-antigens. These cells are trained to respond to foreign antigens, not self-antigens, in the bone marrow and thymus during their development. Earlier, we have explained immune tolerance processes in B cells and T cells.

Genetic susceptibility

Autoimmunity's genetic basis is classified into human leukocyte antigen (HLA) alleles, non-HLA alleles, and monogenic defects. Monogenic defects are the type of Mendelian disorders associated with rare autoimmune diseases.

Celiac disease (CD) and type 1 diabetes (T1D) are significantly associated with HLA DQA1*05 and DQB1*02 alleles encoding the DQ2.5 molecule and HLA DQA1*03 and DQB1*03 alleles encoding DQ8 molecules (Farina et al., 2019). Ankylosing spondylitis (AS) susceptibility and intensity are associated with HLA-B27 haplotypes (Pimentel-Santos et al., 2013). The most susceptible HLA class II alleles to multiple sclerosis (MS) are DRB1*15:01 for Caucasians and DRB1*04:05 and DRB1*15:01 for Japanese (Watanabe et al., 2020). HLA-DRB1*0405, HLA-DRB1*1502, and HLA-DRB1*1602 alleles are related to an elevated risk of developing systemic lupus erythematosus (SLE), while HLA-DRB1*1201 and HLA-DRB1*1202 alleles are associated with a lower risk of developing SLE (Selvaraja et al., 2021). Besides, HLA-DRB1*04 significantly was associated with risk of SLE (Selvaraja et al., 2021).

Studies have shown that several genes orchestrate the maintenance of tolerance to self-antigens. These genes are including AIRE, complement system C4 component, CTLA-4, Fas/Fas-L, FoxP3, IL10/IL10R, IL2/IL2R $\alpha\beta$, and SHP-1 (Cheng and Anderson, 2012; Wu et al., 2009; Facciotti et al., 2020; Lee et al., 2014; Croker et al., 2008). Monogenic defects in AIRE, Fas/Fas-L, and FoxP3 account for APS, autoimmune lymphoproliferative syndrome (ALPS), and immune dysregulation polyendocrinopathy enteropathy X-linked syndrome (IPEX), respectively (Cheng and Anderson, 2012). C4 deficiency is associated with inappropriate immune complex clearance and causes SLE (Wu et al., 2009). IBD and colitis have arisen due to IL10/IL10R and IL2/IL2R $\alpha\beta$ mutations (Lee et al., 2014; Yamanouchi et al., 2007).

The PTPN22, a lymphoid tyrosine phosphatase, negatively regulates the T-cell response. The single nucleotide polymorphism of PTPN22 has been linked to autoimmune conditions such as RA, SLE, T1D, and autoimmune thyroid diseases (Majorczyk et al., 2007; Namjou et al., 2013; Valta et al., 2020; Wu et al., 2020b). NOD-2, IL-23R, and ATG16L1 gene polymorphisms are hereditary risk factors correlated with Crohn's disease (Wildenberg et al., 2017; Rochereau et al., 2021; Xu et al., 2015). AS has been linked to genetic polymorphisms in ARTS1 (Choi et al., 2010). The peptidyl arginine deiminase 4 (PADI4) haplotype is linked to a higher risk of developing RA since it raises the synthesis of citrullinated peptides that function as autoantigens (Suzuki et al., 2003). IL-7 receptor alpha chain-related gene polymorphism is a major risk factor to MS (Gregory et al., 2007). Polymorphisms in the IL2/IL21 locus have been associated with CD (Sherrill et al., 2010). While in patients with SLE, BLK polymorphisms are associated with renal dysfunction (Di et al., 2020), in Mexican patients, the genes BLK and BANK1 are associated with RA susceptibility (Ramírez-Bello et al., 2020). STAT4, IRF5, FC γ RIIB, mannose-binding lectin type 2 (MBL-2), and IL-10 gene polymorphisms are associated with a higher risk of SLE (Wang et al., 2020, 2021; Song et al., 2020; Zhu et al., 2016; Mahto et al., 2020).

Environmental factors

Several environmental factors have been suggested to promote autoimmune diseases, including infection, weather, stress, occupation, smoking, drugs, and diet (Marrie, 2004; Jörg et al., 2016). Also, the consumption of "westernized foods," including intakes high in salt, fat, protein, and sugar, is already associated with an increasing prevalence of various diseases (Jörg et al., 2016; Thorburn et al., 2014). Changes in eating habits have been intensively investigated, showing a direct effect on the gut microbiome leading to immune homeostasis and the gastrointestinal tract (GIT) (Jörg et al., 2016).

One of the most potent environmental compounds related to autoimmunity is silica. The spatial interaction of ANCA-associated vasculitis (AAV) with quarries in an area with a high density of quarries supports the importance of silica as a particular environmental element in autoimmunity (Giorgiutti et al., 2021).

Evidence on the effects of antibiotic usage in childhood on the likelihood of certain autoimmune disorders is missing. The most often used antibiotics had no link to T1D or CD autoimmunity progression within the first four childhood years (Kemppainen et al., 2017).

CTLA4/B7 axis

CTLA-4, also known as CD152, is an inhibitory receptor that aids in maintaining self-antigen immunity. CTLA-4 is structurally and functionally relevant to CD28 since it shares 31% homology and has a higher affinity for the B7 family molecules CD80 and CD86. CTLA-4, on the other hand, has antagonistic effects on T cell activation, and evidence suggests that its inhibitory activity extends beyond the ligand-binding interaction. CTLA-4 competes with CD28 for B7 binding and interacts with clathrin adaptor proteins and tyrosine phosphatases via its cytoplasmic domain to control cell trafficking and set the activation threshold in T cells. CTLA-4 is essential for regulatory T cell function. CTLA-4 has been linked to many autoimmune maladies, including SLE, due to its role in maintaining peripheral tolerance (Romo-Tena et al., 2013). CTLA-4 gene polymorphisms associated with graves syndrome (Esteghamati et al., 2009; Ting et al., 2016), hashimoto disease (Ting et al., 2016), rheumatoid arthritis (RA) (Lei et al., 2005), and T1D (Kavvoura and Ioannidis, 2005). A study reported that the CTLA-4 rs231775 gene polymorphism was linked to a lower risk of RA, while the CTLA-4 rs16840252 and CD86 rs17281995 gene polymorphisms were not (Liu et al., 2021).

In a study to better understand CTLA-4's function in adulthood, Paterson and colleagues (Paterson et al., 2015) developed a model in which tamoxifen-mediated conditional ablation of CTLA-4 can be induced pharmacologically. This study has demonstrated that adult mice with CTLA-4 deletion develop resistance to experimental autoimmune encephalomyelitis (EAE). T_{reg} cells deficient in CTLA-4 produce excessive IL-10 and have greater levels of co-inhibitory receptor expression such as PD-1 and LAG-3. T_{reg} cells without CTLA-4 remain capable of reducing in vitro and in vivo the proliferation of T cells (Paterson et al., 2015).

Abatacept is a soluble fusion protein of CTLA-4 and the Fc tail of IgG that is fully human. Co-stimulation is inhibited by this biological disease-modifying anti-rheumatic drug (DMARD), inhibiting T-cell activation (van Nimwegen et al., 2020). Abatacept-related clinical trials have been done in several autoimmune maladies such as systemic sclerosis (Chung et al., 2020), juvenile idiopathic arthritis (Ruperto et al., 2008), sjögren's syndrome (SS) (van Nimwegen et al., 2020), T1D (Orban et al., 2011), RA (Genovese et al., 2005), and SLE (Group TAT, 2014).

FOXP3

Foxp3 is a critical regulator of T_{reg} cell gene expression responsible for most of these cells' suppressive ability. The coordinated activity of transcription factors and comprehensive epigenetic control mechanisms regulates Foxp3 expression in T_{reg} cells; additionally, post-translational modifications modulate Foxp3 activity. Besides T_{reg} cells, Foxp3 expression has been shown on activated CD4⁺ T cells, CD8⁺ T_{reg} cells, natural killer T cells (NKT), macrophages, B cells, and cancer cells (Lu et al., 2017). Cytokines such as TGF- β and IL-2 and other elements in the tissue microenvironment like retinoic acid, vitamin C, and short-chain fatty acids (SCFAs) can positively affect the induction and maintenance of Foxp3 transcription (Lu et al., 2017; Yue et al., 2016; Hill et al., 2008; Arpaia et al., 2013; Chen et al., 2011). In comparison, pro-inflammatory cytokines such as TNF and IL-6 and other stimuli such as Toll-like receptor (TLR) activation or robust T cell receptor (TCR) and co-stimulatory molecule signaling have a negative effect on Foxp3 (Lu et al., 2017; Gerriets et al., 2016; Nie et al., 2013; Gao et al., 2012). Foxp3 gene expression is initiated and stabilized by hierarchical and synchronized Foxp3 conserved non-coding sequences (CNSs) such as CNS0 and CNS3 activation, which is essential for T_{reg} cell growth, maintenance, and immunological self-tolerance. CNS0 and CNS3 deficiency results in fatal autoimmunity. Foxp3 expression is induced and maintained by CNS0 in an IL-2-dependent manner (Kawakami et al., 2021).

AIRE

In thymic epithelial cells (TEC), AIRE mediates the expression of tissue-specific antigens (TSAs) to facilitate tolerance against self-reactive T lymphocytes. Brg1 allows AIRE to act by promoting accessibility at loci encoding tissue-specific antigens. Brg1 promotes peripheral-tissue-specific gene accessibility while AIRE suppresses it. In medullary TEC, the effects of AIRE and Brg1 on chromatin state are opposed (Koh et al., 2018).

Biomolecular assemblies that resemble aggregates are evolving as modern practical conformational states. AIRE assembles into broad aggregates that can be used as nuclear foci. AIRE forms filamentous homo-multimers in vitro using its caspase activation recruitment domain (CARD), and that this assembly mediates foci forming and transcriptional function. AIRE mutants shape foci with enhanced promyelocytic leukemia protein (PML) body association. AIRE's transcriptional function is impaired as it is directed to PML bodies, but it is restored when PML bodies are dispersed with a viral antagonist (Huoh et al., 2020).

Multiple endocrine defects, chronic mucocutaneous candidiasis, and high serum autoantibody titers characterize APS1, a monogenic recessive condition. An APS1 mouse model was used to test the effectiveness of adeno-associated virus serotype 9 (AAV9)-AIRE (AAV9 bearing AIRE cDNA) gene therapy. AAV9-AIRE was injected intrathymically and showed strong transduction ability, restoring AIRE expression in the thymus. In treated versus control mice, AIRE gene transmission resulted in a substantial improvement in TSA expression and, more significantly, a significant decrease in serum autoantibodies (Almaghrabi et al., 2020).

FAS/FAS-L pathway

Fas (also known as CD95 or APO-1 or TNFRSF6) and Fas-L belong to TNF-R and TNF superfamily, respectively. The initiation of a caspase cascade that initiates apoptosis occurs when Fas is ligated with Fas-L. Fas-FasL-mediated apoptosis or activation-induced cell death (AICD) is an effective pathway for immune homeostasis maintenance. Programmed cell death (apoptosis) plays an

important function in a physiological immune response by removing potentially pathogenic autoreactive lymphocytes from the bloodstream and tissues, reducing the tissue damage that immune responses eventually do. When Fas binds, the protein adaptor Fas-associated death domain (FADD) of procaspase-8 is recruited and activated, resulting in the forming of the death-inducing signaling complex (DISC). Active caspase-8 cleaves caspase-3 immediately, triggering the caspase cascade, which results in cell death (Volpe et al., 2016).

MRL-lpr/lpr mice have mutations in the Fas gene and are used to study autoimmune maladies, including SLE, RA, SS, and ALPS (Yamada et al., 2017). In MRL-lpr/lpr mice, Fas-mediated apoptosis of peripheral T cells, which is a critical mechanism for maintaining immunological tolerance, is inhibited. In MRL-lpr/lpr mice, AICD fails to delete peripheral T cells, resulting in an uptick in autoreactive T cells, which causes autoimmune lesions to develop in several organs (Yamada et al., 2017; Singer et al., 1994). ALPS patients also have mutations in the Fas gene (Hsu et al., 2012).

Mice with the gld/gld genotype have mutations in the gene that codes for Fas-L, and they are commonly used as an autoimmune disease model (Nagata and Suda, 1995). Since some enzymes allow Fas-L to be shed from the cell surface, it is unstable (Garcia et al., 2013). When soluble Fas-L (sFas-L) binds to Fas, it causes cell proliferation rather than apoptosis (Herrero et al., 2011).

Autoreactive CD8+ T cells

Autoreactive CD8⁺ T cells tend to be essential players in various animal models of autoimmunity such as T1D and MS in the non-obese diabetic (NOD) mouse and EAE mouse, respectively; their roles in human autoimmune disorders are still being investigated. Autoreactive CD8⁺ T cells can serve as pathogenic effector cells, causing tissue damage, while other autoreactive CD8⁺ T cells can act as regulators, protecting the body from autoimmune attacks (Tsai et al., 2008). Activated CD8⁺ T cells as a juggernaut can destroy target cells via the Fas/Fas-L pathway or release cytolytic granules at the effector/target cell junction. TNF and IFN- γ are two pro-inflammatory cytokines secreted by activated CTLs that can trigger tissue harm (Tsai et al., 2008).

Type 1 diabetes mellitus (T1DM), or autoimmune diabetes, is a progressive condition that causes hyperglycemia due to insulin deficiency caused by pancreatic-cell failure (Katsarou et al., 2017). This malady is characterized by a CD4⁺ and CD8⁺ T cell-dependent autoimmune pathway that directly targets the pancreatic β -cell (Katsarou et al., 2017). Epidemiological experiments have demonstrated that inheriting specific human MHC class I alleles, such as HLA-A*0201, increases the hereditary susceptibility to T1D when expressed with particular MHC class II alleles (Tsai et al., 2008). In order to identify the effect of type of autoreactive CD8⁺ T cells phenotype on T1D progression, a study has revealed that autoreactive T cells were phenotypically diverse, and their phenotype varied with disease progression rate (Wiedeman et al., 2020). Also, in subjects with T1D who underwent rapid loss of C-peptide, activated islet-specific CD8⁺ memory T cells were prevalent (Wiedeman et al., 2020). In the islets of non-obese diabetic mice, IL-21 controls SOCS1 expression in autoreactive CD8⁺ T cells, but it is not needed for CTL activity acquisition (Sutherland et al., 2019).

Molecular mimicry and infectious agents

Molecular cross-reactivity is the existence of common bacterial and pathogenic or toxic agent epitopes in molecular response to Microorganisms that mimic the host molecules, which is known as pathogenesis. The molecular mimicry was seen to exist in various ways, including complete protein identification, protein level homology, amino acid sequence similarity, and structural similarity. The mimicry between *Campylobacter jejuni* lipooligosaccharide (LOS) and human GM1 ganglioside, as well as the mimicry between the dietary antigen butyrophiline and myelin oligodendrocyte glycoprotein, are two examples of molecular mimicry (Peterson and Fujinami, 2007).

Group A Streptococcus (GAS) antigens stimulate antigen-specific B and T cells after GAS adhesion to and penetration of the pharyngeal epithelium. An autoimmune reaction may result from a molecular mimicry between GAS group A carbohydrate or serotype-specific M protein and the host heart, brain, or joint tissues, which triggers the clinical manifestations of acute rheumatic fever (ARF) (Carapetis et al., 2016).

It has been shown that viruses such as Epstein-Barr virus (EBV), Coxsackie virus, and human T-lymphocyte virus (HTLV) are linked to the development of SLE (Singh et al., 2013). In lupus patients, EBV infection causes the synthesis of the viral protein Epstein-Barr virus nuclear antigen-1 (EBNA-1) antibodies, which cross-react with lupus-associated autoantigens such as Ro, Sm B/B', and Sm D1 (Poole et al., 2006). In SLE patients, anti-C1q antibodies against the main antigenic residues of C1q known as A08 directly cross-reacted with the EBV-related EBNA-1-derived peptide EBNA348 (Csorba et al., 2019). Anoctamin 2 participates in an EBNA-1-associated molecular mimic, which is a decisive etiopathogenesis factor in MS (Tengvall et al., 2019). It was shown that the Coxsackievirus B1 virus was correlated with an enhanced risk of β -cell autoimmunity. CVB3 and CVB6 were not previously thought to be associated with β -cell autoimmunity; however, the new research found that CVB3 and CVB6 positively affect decreasing it (Laitinen et al., 2014).

HTLV-1 infection results in antibody response to HTLV-1-tax protein. Tax-specific antibodies, which are immunodominant for its C terminus, cross-react with the M9 sequence of heterogeneous nuclear ribonuclear protein A1 (hnRNP A1), expressed by CNS, especially corticospinal neurons. This immune response inhibits neuronal firing, potentially leading to neurodegeneration and death (Lee et al., 2005).

A particular immunologic cross-reactivity was seen in the human acetylcholine receptor (HuAChR) alpha-subunit 160–167 residues, with the homologous domain of herpes simplex virus (HSV) glycoprotein D, residues 286–293. This cross-reaction supports the hypothesis that HSV being associated with the onset of the myasthenia gravis (Schwimmbeck et al., 1989).

Epitope spreading

Epitope spreading (ES) phenomenon is the emergence of an immune reaction to epitopes other than the disease-causing epitope that are non-cross reactive (Powell and Black, 2001). ES is not a trait exclusive to systemic autoimmune maladies. Additionally, it has been identified in T cell-dependent organ-specific autoimmune disorders such as T1D, MS, and EAE (Monneaux and Muller, 2002). In autoimmune diseases, there are two main pathways as regards ES, including independent and dependent. Tissue injury, inflammation, and cytokines provoke T cells to detect cryptic epitopes and trigger B cells in the “independent” pathway. A “dependent” pathway, on the other hand, is dependent on the processing and presentation of physical antigens to activate T and B cells (Didona and Di Zenzo, 2018). ES can also be induced in response to some pathogen; antigen release and intermolecular ES may occur due to viral and other cytolytic infections (Ruff et al., 2020). In EAE mouse models, an investigation was conducted to indicate that naive T cells are recruited to the inflamed CNS and are activated by local APCs such as DCs, beginning ES (McMahon et al., 2005).

Glossary

Bacteriophages A virus that infects and replicates within bacteria and archaea.

Variable lymphocyte receptors (VLR) A group of receptors with the Leucine-rich repeat (LRR) property which mediate adaptive immune responses in the jawless vertebrates, lampreys and hagfish.

Natural killer T cell (NKT cells) A heterogeneous group of T cells that share properties of both T cells and natural killer cells which recognize an antigen-presenting molecule that binds self and foreign lipids and glycolipids.

Gamma delta T cells ($\gamma\delta$ T cells) A less common subset of T cells that have a distinctive antigen receptor (made up of one γ and one δ chain) and they are mainly located in the gut mucosa and have prominent role in recognition of lipid antigens.

Mucosal associated invariant T cells (MAIT cells) A subset of T cells with special MHC class I-like protein presenting foreign antigens like bacterially produced vitamin B metabolites.

B1 cells A subset of B cells with marker profile of CD20 + CD27 + CD43 + CD70- recognize and produce antibody against more types of antigens including intracellular antigens.

Marginal zone B cells This subset of B cells with profile CD19 + CD27 + IgD + IgM^{high} is non-circulating mature B cells that locate in marginal zone of the secondary lymphoid organs.

Piwi-interacting RNA (piRNA) This is the largest class of small non-coding RNA molecules expressed in animal cells and are mostly involved in the epigenetic and post-transcriptional silencing of transposons and other repeat-derived transcripts.

Follicular helper T cells (TFH) This subset of CD4 + T cells are antigen-experienced T cells in B cell follicles of secondary lymphoid organs and upon cross-signaling with their cognate B cells, TFH cells trigger the formation and maintenance of germinal centers.

Rh blood group, D antigen (RHD) This membrane protein is cluster of differentiation 240D (CD240D) that expressed in erythrocyte and define blood group system.

Toll-like receptors (TLRs) These single, membrane-spanning receptors are a class of proteins that play a key role in the innate immune system that recognize structurally conserved molecules derived from microbes.

Cytosine triphosphate deoxynucleotide oligodeoxynucleotides followed by a guanine triphosphate deoxynucleotide (CpG) This is a unmethylated short single-stranded synthetic DNA molecule that contain a cytosine followed by a guanine which a phosphodiester link between consecutive nucleotides.

Fragment, crystallizable region (Fc) receptor This is a protein found on the surface of certain immune cells bind to antibodies that are attached to infected cells or invading pathogens.

Historically the ability of memorization in the immune system was the first characteristic that hints early scientists nearly 2500 years ago to propose the presence of immunity. Greek historian "Thucydides" mentioned the powerful secondary response survivor of the plague of Athens in the returns of the disease around 430 BC (Doherty and Robertson, 2004). Theory of recognition and remembering previously encountered diseases, however, described as adaptive immunity by "Rhazes" 930 CE when he refers to when a disease affects only children in a family but not affecting the parents caring for the patient (Doherty and Robertson, 2004).

During the last 50 years, we now define the immunologic memory as the second goal of immune components after successful primary immune response and termination of infection using short-lived effector cells. To achieve this goal, immunity creates a quantitatively and qualitatively advanced response (with higher speed or more robust and stronger) than the first encounter. Until less than a decade ago, our knowledge regarding immunologic memory was restricted to T and B cells since they were capable to rearrange their cell receptors for unique antigen specificity, and generate long-lived memory cells, however, the new evidence suggests that prokaryotes and other eukaryotes without these adaptive immune cells can also possess memory traits (Table 1) (Sun et al., 2014).

Table 1 Immunological memory from prokaryote to higher vertebrate.

Immunity	Prokaryotes	Invertebrates eukaryotes	Lower vertebrate eukaryotes	Higher vertebrate eukaryotes
Receptors	CRISPR–Cas (genetic elements)	Toll, DSCAM, (antigen receptor)	VLRA, VLRB, VLRC (antigen receptor)	TCR, BCR (antigen receptor)
Mechanism of diversity	CrRNA	?	Leucine-rich repeats	VDJ recombination
Specificity	Yes (sequence specific elements)	Yes	Yes	Yes
Immune memory	Yes	Yes	Yes	Yes

CRISPR: clustered regularly interspaced short palindromic repeats, CAS: CRISPR Associated protein, CrRNA: CRISPR transcript, DSCAM: Down syndrome cell adhesion molecule, VLR: variable lymphocyte receptor, TCR: T cell receptor, BCR: B cell receptor, VDJ: variable, diverse, and joining regions.

Immunologic memory in prokaryotes

Prokaryotes including ~50% of bacteria and almost all archaea present an adaptive immunity against infectious genetic elements (e.g. viruses, bacteriophages and plasmids) using CRISPR–Cas (clustered regularly interspaced short palindromic repeats–CRISPR associated) system (Labrie et al., 2010). CRISPR–Cas is a complicated mechanism that prokaryotes use to silence foreign nucleic acids upon the re-infection of the specific invader. CRISPR genomic loci are like a library in the genome of prokaryotes recording, in a very well managed format, a segment of infectious nucleic acids originated from viruses or plasmids in the first encounter (Westra et al., 2012). The process of adaptation and incorporating of the foreign nucleic acids is known as spacer acquisition. Subsequently, the CRISPR locus is transcribed to produce a transcript of captured foreign nucleic acids that becomes processed into short RNAs (Charpentier et al., 2015). This transcribed short RNAs at the time of the second infection can target the foreign nucleic acids and interfere with their complementarity sequence with the help of Cas proteins (Fig. 1) (Brouns et al., 2008). Although 20% of CRISPR library contains spacers originating from the host's genome suggesting other functions of the CRISPR–Cas in endogenous gene regulation, spacer acquisition was evident to be significantly dependent on DNA replication and invader-derived nucleotide acids have 100–1000-fold higher affinity for acquisition versus self-derived spacers (Levy et al., 2015).

Immunologic memory in invertebrates and low vertebrates

In eukaryotes also recent evidence changed our previous thoughts that only early jawed vertebrates pose adaptive immunity due to attaining the antigen receptor diversification machinery. Although in 1960s some experiments on “sea lampreys” suggested antigen-specific agglutinating antibody and delayed-type hypersensitivity against bacteria and second skin allografts (Finstad and Good, 1964), after almost 20 years variable lymphocyte receptors (VLRs) in primordial lymphocyte-like cell subsets and receptors (mainly in the surviving jawless fish or agnathans) were described (Boehm et al., 2012). Despite the common consensus for evaluation of innate immunity in invertebrates (>97% of known species in the animal kingdom), in the early 21st century an adaptive immunity and resistance to subsequent infection were discovered in crustacean species against a parasitic tapeworm (Kurtz and Franz, 2003). During the recent 15 years, more evidence has been provided regarding adaptivity immunity in invertebrates including somatic re-combinatorial diversity (in immunoglobulin superfamily domains of hemolymph proteins of freshwater snail) (Zhang et al., 2004), pathogen-specific splice variant repertoires (of pattern recognition receptor in Anopheles mosquitoes against malaria (Dong et al., 2012), stronger established Toll pathway (in primed fruit fly against secondary bacterial challenge with *Streptococcus pneumoniae*) (Pham et al., 2007) and improved circulating granulocyte numbers (in the Gambiae mosquitoes following the primary infection against *Plasmodium falciparum*) (Rodrigues et al., 2010). Another sophisticated adaptive immune response has been labeled as “olfactory imprinting” where immune networks of invertebrates (mainly worms) activated during first encounter with pathogen influence nervous system memory (e.g. dopaminergic neurons/receptors or epigenetic memory mediated by piRNAs) to avoid subsequent toxic exposure (Anyanful et al., 2009; Inoue et al., 2013; Shirayama et al., 2012). Although many aspects of the nervous system–immune system cross-talk remains to be clarified, evidence such as these indicate that efferent neural circuits that recognize injury or infection modulating immune reaction and impact immune memory (Tracey, 2009).

Non-B non-T immunologic memory in higher vertebrate

A strong plethora of studies supports the importance of innate immune cells crosstalk for the development and programming of the adaptive immune system. New additional insights, however, identified intrinsic immunologic memory of the RAG-dependent “innate” lymphocytes (NKT cells, $\gamma\delta$ T cells, mucosa-associated invariant T cells or MAIT, other “non-classical” T cells, B1-B cells and

Fig. 1 CRISPR defense mechanism in prokaryotes including bacteria and archaea including spacer acquisition (naive or primed Cas dependent), integration, transcription, processing (three different types) and interference providing general adaptive immunity with memory against invader genetic elements. R = repeated sequences, L = leader sequences, arrows = incorporated spacer sequences.

marginal zone B cells) and RAG-independent “innate lymphoid cells” (ILC1-NK cells, ILC2, and ILC3) (Spits et al., 2013). These data showed that these innate cells may not restrictively respond rapidly and non-specifically with the production of short-lived cells, a phenomenon that further blurring the previous misconception that separated innate from adaptive immunity. Still, the physiological mechanism for imprinting at a genetic level by initial stimulation and epigenetic modifications of these cells is not very well illustrated. However, the first line of evidence has been rooted in the role of NK cells in hybrid resistance and intense/rapid rejection in a pre-treated receiver of parental bone marrow graft compared to graft from the other parent (Cudkowicz and Stimpfling, 1964). In the following years after this experiment, immunologists discovered NK cell specificity and memory against a wide range of antigens (particularly in anti-viral immune responses) including species-specific limited-repertoire against cytomegalovirus which can lead to the generation of long-lived memory NK cells (Sun et al., 2009; Sun and Lanier, 2009). Interestingly, memory NK cells could perform self-renewal (persist for years by maintaining IL-15 signals), and susceptibility to locate within the spleen and create better secondary responses (by production of activating CD94/NKG2C receptor, IL-12 and STAT4 early pro-inflammatory cytokines and producing IFN- γ more robustly than resting NK cells, Fig. 2) (Firth et al., 2013; Foley et al., 2012; Romee et al., 2012; Sun et al., 2010). Further, this notion was backed up with studies that evaluated NK-cell clonal proliferation and memory in a wide range of viral models in mice, including vaccinia virus (Gillard et al., 2011), influenza virus (van Helden et al., 2012), and herpes simplex virus infection (Theyerl-Abele et al., 1990). Moreover, CXCR6-expressing NK cells residing in the liver in primed RAG-deficient mice with specific antigens of viral infections (e.g. influenza and HIV) can result in secondary challenge protection (Paust et al., 2010). Memory function of $\gamma\delta$ T cells against homologous *Listeria* bacteria challenge, but not against a heterologous bacterium (Sheridan et al., 2013), modulated longevity of macrophage or dendritic cell subsets like Langerhans cells with longer half-life tissue residency due to their adopted Toll-like or Nod-like receptors or intracellular sensors (Sun et al., 2014) suggesting that other innate immune cells and even cells derived from the myeloid lineage have characteristic resembling adaptive immunity.

Fig. 2 Pathways of priming of adaptive immune and memory cell generation in NK cells during Hapten-sensitization, cytokine stimulation (increased inflammatory response after cytokine priming of IL12, IL15 and IL18) and viral infections (long-lived cells after contraction phase dependent of IL-15 and microRNA-155).

Humoral immunologic memory in higher vertebrate

Given the cornerstone role of B and T cells in the adaptive immunity of higher vertebrates up to mammals, immunologic memory is tightly connected with the function of these cells. The first important component that provides non-lifelong antigen-specific protection for a long period is short-lived plasma cells (PCs) since that can generate high-affinity pathogen-specific antibodies in the reticuloendothelial system and mucosal surfaces preventing reinvasion for several months. Their produced antibodies harmonize innate and adaptive immunity and improve immediate neutralization and rapid opsonization against seasonal viral infection which minimizes the pathogen load in wintertime. However true memorization can be assigned to long-live PCs located in bone marrow (which produce less compared to short live PC). These long-live PCs make the steady-state level of immunoglobulin in the healthy individual and they receive their long-term survival signal by interaction with IL-6 secreting stromal cells. However, if the secondary pathogenic encounter happens, the new antibody-antigen complex enhances the apoptosis in old PC in bone-marrow and replace them by competition toward stromal cells by newly generated more-specific PCs (Nutt et al., 2015).

A higher level of complexity in adaptive immunity poses by long-lived memory cells which can both be identified in humoral and cell-mediated memory. B and T memory cells develop inside of secondary lymphoid tissues and originate during the first activation of naïve T and B cells in the primary response. If these memory cells survive till the secondary infection their stochastic frequency is 10–100 folds higher than naïve compartment with the same T cell or B cell receptors. Memory cells signaling machinery retain the ability of response with accelerated kinetic compared to naïve cells (higher co-stimulatory molecules and therefore receive more cognate interaction for proliferation), improved antigen presentation (in case of memory B cells [MBC] higher level of MHC-class II complex) and have a better antigen recognition due to prior somatic hypermutations and improved affinity. These advantageous mechanisms in MBCs together with their anatomical localization facilitate their rapid differentiation toward new PCs generation within 4 days in secondary immune response (still with capacity for class switching recombination and further somatic hypermutation for better refinement) compared to 8 days in the primary response. Another important inhibitory mechanism by Fc receptor $\text{Fc}\gamma\text{RIIB1}$ on naïve B cells suppressing activation of naïve B cells which guarantees the proliferation of MBCs in the secondary antigen exposure and continues the repetition of antibody development for successive infections with the specific pathogen by age. Altogether the memory generation leads to decreasing the rate of infection in children (normally with 5–10 episodes per year) compared to adults (normally with 0–2 episodes per year) (Kurosaki et al., 2015).

Regulation of MBCs and effector PCs differentiation in the first infection takes place in two anatomical places of secondary lymphoid organs including pre- and post-germinal center (pre-GC and post-GC). In the pre-GC responses, at the T-B border region activated B cells choose between initiating the GC, short-lived PCs or MBCs generation, but in post-GC, the fates of activated B cells

are migration to the dark-zone, long-live PCs or MBCs generation (MacLennan et al., 2003). Recent studies showed that most of the clones against different epitopes of specific pathogens have only one fate (only 10% of clones can generate fate subsets) and this is tightly connected with the strength of signals that B cells receive from the receptor (Fig. 3). The stronger affinity of antigen receptor determines the PC generation (by enhanced expression of BAFF receptor, RelA, Blimp1, PRDM1, IL-4 and anti-apoptotic factor MCL-1) and intermediates signal favor GC- or dark-zone migration, in pre or post GC responses (by increased expression of BCL-6), respectively. Of note, if the signal of B cell receptor is slightly over than apoptotic threshold, then it presents the memory fate (with lower metabolic activity and less specific antigenicity, low IRF4 expression, upregulated BCL-6 in response to IL-21 and expression of MITF, PU.1/IRF8, and BACH2) (Shinnakasu and Kurosaki, 2017).

MBCs constitute multiple subsets but all express CD27 on their surface and they are reactive in secondary lymphoid tissues with cognate interaction with pathogen-specific effector CD4 TFH cells to produce new MBCs with higher average affinity and effector PCs. IgM only (IgM + IgD-CD27+) and class-switched (IgD-IgM-CD27+) MBCs are GC-dependent and thus they classify as classical MBCs with somatically mutated Ig V genes. However, IgM + IgD + CD27+ MBCs can be both the result of T-dependent GC response (the majority of this subset with BCL6 expression) and non-MBCs independent of GC (a minority of this subset with TLR signaling dependency and location in the marginal zone of spleen and bone marrow) (Tangye and Good, 2007). Among classical MBCs, IgM-only MBCs are longer-lived, propagate more and re-enter secondary GC for further class switching and diverse their BCR (higher level of FOXP1) but class-switched MBCs disappear faster and preferentially direct to PCs generation (higher level of IRF4, CD80 and PDL2) (Pape et al., 2011). Typical MBCs recirculate between secondary lymphoid organs (expressing RUNX1) and they localized later to inflamed tissue (expressing TBX21 and CXCR3) or re-enter GC in a secondary infection (expressing CCR6). IgA + MBCs also prefer localization in the mucosal epithelium and mucosa draining lymph node (expressing ROR α and CCR1/CCR5). Of note, IgE+ MBCs rarely arise from subsequential switching since autonomous GC formation toward IgE signaling actively prevent IgE+ MBCs and long-term PCs by apoptosis. Therefore, the IgE level of normal individuals is the lowest level of serum immunoglobulin (Talay et al., 2012).

Of note, the memory process of humoral immunity gain insight toward several pathologic events and therapeutic strategy. A physician can treat hemolytic anemia of the newborn due to discordant Rhesus D between mother and fetus by injection of IgG anti-RhD (RhD) antibodies or RhoGAM which mimic secondary immune response and suppress activation of naïve B cells and

Fig. 3 Pathways of priming of naïve B cells and relocation of the generated memory B cell (MBCs) based on the threshold of B cell receptor (BCR) signaling in pre and post germinal center (GC) reactions. BCR = B cell receptor, DC = dendritic cells, DZ = dark zone, FDC = Follicular dendritic cells, PC = plasma cells.

MBCs generation in mothers with RhD-. This should be performed when they might encounter red blood cells of their RhD+ fetus at 28th week of pregnancy and 3 days after delivery to prevent MBCs generation (Brinc and Lazarus, 2009). The suppression of naïve B cells activation in the secondary immune response is also challenging for pathogens that change their epitope to escape immune response, mainly influenza virus, and it may lead that after several years all epitopes will be not-recognizable for MBCs and cause full-blown influenza and simulate primary immune response since they need activation of naïve B cells (Chen et al., 2018). Although self-reactive post-GC class-switched MBCs are more abundant in peripheral blood of normal individuals, proliferation of an activated group of CD27-IgD-CD95+ MBCs with a predisposition to differentiate into IgE+ PCs correlates with biomarkers in serum and disease severity of autoimmune disorders (Butt et al., 2015).

Cellular immunologic memory in higher vertebrate

During a primary response of cellular immunity, 95% of each activated naïve T cells (1 to 50,000 cells proliferation) will be effector and only 5% has potential for long-term survival and escape apoptosis during contraction phase as memory T cells (MTCs expressing IL7R and BCL2 which is essential for the cell renewal). These cells persist in either secondary lymphoid organs (central MTCs) or in the recently infected peripheral tissue (effector MTCs and tissue resident MTCs, Fig. 4) (Wakim and Bevan, 2010). Central MTCs express L-selectin or CD62L and CCR7 chemokine receptors which allow them to enter secondary lymphoid organs and being activated slowly by antigens presented and cytokine produced by antigen-presenting cells. Central MTCs also presents a higher tendency for activation combined with increased capacity for IL-2 secretion, cellular expansion and differentiation to T effector cells. In contrast to central cells, effector and tissue specific MTCs are already differentiated and do not circulate through lymphoid organs but due to expression of CCR6, CCR4, CXCR3, CCR5 can enter mucosal tissues and inflamed regions patrolling peripheral tissues response immediately to in site infection (Pepper and Jenkins, 2011). MTCs have common features including evidence of previous activation, independency to cognate antigen and co-stimulation with CD28 (compared to naïve compartment T cell) and enhanced function upon re-exposure to the specific antigen. MTCs is well-studied in CD8+ compartment (surface

Fig. 4 Pathways of priming of naïve T cells and relocation of the generated memory T cell (MTCs) based on the phase of infection and the function of generated MTCs.

markers, epigenetic profile and metabolic states), but less characterized in CD4+ T cells due to high inherent plasticity and diverse polarity (TH1, TH2, TH17, TFH) as well as rapid decline in number over time compared to CD8+ MTCs (Chang et al., 2014). Contrary to MBCs, MTCs and naïve T cells both can be stimulated in the secondary immune response but MTCs contribution is more pronounced. Among MTCs two other subsets have been discovered recently including stem cell MTCs (low level of IFN- γ and IL2 with potential to self-renew and the multipotent programming machinery to diverse polarization of effector and memory subsets) and regulatory MTCs (previously activated FOXP3 T cells required for mitigation of tissue damage during the function of pro-inflammatory MTCs and reinforcing of fetal tolerance during pregnancy) (Rosenblum et al., 2016).

Intriguingly, the memory process of cellular immunity gain insight toward several pathologic events and therapeutic strategy. How MTCs are produced and kept long-term is an essential question were can help immunologist to treat autoimmune disorders using regulatory MTCs and cancer and metastasis using tissue resident MTCs. By studying MTCs we understood that systemic vaccine can be improved by the concomitant injection of adjuvant molecules into the targeted peripheral tissues or used for tumor treatment (Mueller and Mackay, 2016; Rosenblum et al., 2016). Few studies also suggested that treatments promoting the generation of stem cell MTCs could induce more durable and effective T cell-based immunotherapies (Kugelberg, 2016).

Using the state of art of humoral and cellular immunological memory, the theory of protection before infection (vaccination) becomes reality before knowing the complete mechanism. Induction of primary immune response and generation of immunological memory with a harmless form of the pathogens stimulate protective adaptive immunity which has been practiced in China 1000 CE using crusts of smallpox lesion (Doherty and Robertson, 2004). In 1796 these practices were reconsidered by Edward Jenner using variolation (variola: Latin name for pustule, intranasal or intradermal confrontation with pustule of the patient with risk of death $\sim$ 1:100) or inoculation with cowpox (vacca: Latin name for cow, due to antigen mimicry of natural safe relative) to prevent smallpox infection. Hence the term vaccination arose and lead to the global eradication of smallpox in the 20th century due to long life immunity. However long-life immunity is not achievable for all pathogens since this aim needs vaccination via the same pathologic route of infection, conserved antigenicity of the pathogen and no animal reservoir for the pathogen. Moreover, immunologic components including memory PCs and MTCs against those pathogens should remain in the circulation (e.g. measles and smallpox stay for 75 years) but for the majority of pathogens due to non-optimal vaccination conditions (antigen-independent survival due to IL7 and IL15 signaling are dropped down e.g. diphtheria halved after 19 years), the immunization should be repeated for maintenance or re-generation of memory cells.

Application of immunologic memory and vaccination

Louis Pasteur and Emile Roux in 1880 showed immunity could be induced against cholera using attenuated cultures (Doherty and Robertson, 2004) which provide inactivation of the pathogen virulence while preserving its immunogenicity. Live attenuated vaccines were later produced by an infection in non-human cell lines to adopt them with new cell lines. A mutant form of live viruses that grow poorly in humans were also other versions of attenuated vaccines that pose a better immunity compared to totally inactivated viruses since they infect to some extent target cells mimicking real infections. Among those anti-viral vaccines, oral polio vaccine (OPV, sabin), measles, mumps and yellow fever are well known worldwide. Some anti-bacterial vaccines (e.g. bovine strain against *Mycobacterium tuberculosis* and salmonella typhi with a mutation in an enzyme necessary for LPS synthesis) are nowadays in common medical practices. Killed or inactivated pathogens can be produced as vaccines using chemical components (with formalin) or physical methods (with heat or irradiation) against viruses (influenza, rabies, polio in IPV from) bacteria (formalin embedded bacterial toxins diphtheria and tetanus called toxoids and *Bordetella pertussis* cause of whooping cough) (Greenwood, 2014). Combination of inactivated and live attenuated virus were also gain some achievement to solve side-effect of OVP Sabin strain 3 and back-mutation making wild type polio during vaccine manufacturing or after vaccination in prolonged replication in an individual with immunodeficiency. Recently the new strategy of combining IPV and OPV has been suggested to make the first dose with an inactivated vaccine which may generate memory and antibodies again strain 3 and then boosting vaccination can be continued with trivalent OPV (Tang et al., 2018). The other generation of vaccines is recombinant DNA technology to produce a subunit vaccine. This new method usually targets surface molecules of the pathogens to generate neutralizing antibodies with the highest protective repertoire to discover superior antigens. The most significant examples are HBV vaccine using surface antigen from baker's yeast culture (85% of vaccinated people are protected), rotavirus (against 5 major cattle or most common VP4 and VP7 assortment) and meningococcus vaccine.

To improve the quality and quantity of memory generation vaccination conjugate and the adjuvant vaccine can be helpful. To stimulate high-affinity antibodies against polysaccharides antigen and improve feeble T-cell independent B cell response which gave rise to low-affinity IgM antibodies and no MBCs, som carbohydrate from the other capsids of encapsulated bacteria (including pneumococcus, *Salmonellae* spp., meningococcus, *Hemophilus influenzae*, *Escherichia coli* and *Klebsiella* spp.) can be conjugated by tetanus or diphtheria toxoid. This method improves the interaction of naïve B cell-specific for an epitope of bacterial polysaccharide by endocytose of the intact conjugate and accelerates processing of the toxoid. Therefore, they present peptide antigens to the activated toxoid specific TFH which drive GC reactions and produce high-affinity antibodies and long-term MBCs. The adjuvant component can be added to stimulate innate immunity via TLR and pattern recognition receptors to mimic inflammation required for the initiation of the adaptive immune response. Mainly alum aluminum hydroxide is the adjuvant used in tetanus or diphtheria vaccines (DT vaccine), although this adjuvant is not effective as conjugate form with pertussis carbohydrate (DTP). Other newly

invented adjuvants include oil-in-water MF59 and virosomes, TLR agonists (CpG nucleotides, PolyIC RNA analogs, flagellin, Pam3Cys lipopeptide) which may improve vaccination quality in the future (Zimmermann and Lepenies, 2015).

Introduction to inflammation

Understanding the role of inflammation as a function of clinical disease states has become invaluable in design of treatment modalities and the development of therapeutics. A greater knowledge of inflammatory responses at all levels of disease is critical for health care workers, physicians, and students of all biological systems. Inflammation is critical for everyday health and homeostasis, without which the body cannot discern regular biological turnover and events from outside interference that causes harm. I.R. Cohen stated it most directly when he wrote “The function of the immune system is to produce inflammation commensurate with the body’s need to keep itself fit for living” (Segel and Cohen, 2001).

There is a basic assumption that the objective of the immune response is to protect an individual from pathogenic assault. However, when closely examined, inflammation as part of the immune system involves factors for both protection and health maintenance. Protection is the outcome of an immune-regulated response to non-host molecules, with the end result triggering production of factors involved in effector processes. Inflammation is a by-product of those early induced events, where it functions primarily to elicit reactive mechanisms that clear pathogens. Longer term, well-regulated inflammation is also critical for homeostasis. These pathways are critical for effector maintenance, such as normal cellular turnover during aging, healing of tissue due to trauma, and keeping the immune response in a “ready” state of surveillance to guard against unwanted pathogenic components that may enter the body.

Inflammation: A working definition

It is critical to define “inflammation” to allow discussion of responses to be placed within a clinical or pathological setting. A simplistic working definition includes the response of living tissue to damage or assault of any kind. At its root, inflammation

[☆]Modified in part from *Translational Inflammation*. Csencsits-Smith, K. and Actor, J.K. Elsevier, Philadelphia, PA. December 2018. ISBN-13: 978-0128138328; ISBN-10: 0128138327.

Fig. 1 Biological elements of inflammation. Multiple parameters drive the inflammatory response, leading to development of pathological consequences and clinical disease states.

represents a response to insult of or to vascularized tissues, with a purpose to deliver defensive materials (blood cells and fluid) to a site of injury (Kumar et al., 2017; Actor, 2014; Murphy and Weaver, 2017; Owen et al., 2013). Main components of inflammation revolve around vascular reactions and cellular responses that activate and release chemical or cell-derived mediators. A strong feedback mechanism controls active participation of leukocytes and factors involved in maintaining healthy tissue status (Fig. 1). Upon injury, released factors in the form of chemical mediators diffuse from the region to function on vascular beds, triggering endothelial cells to alter surface conformation to manipulate delivery of circulating factors and cell populations into subvascular space. A process ensues whereby chemotactic factors allow activation in localized blood vessels (capillaries, venules, or arterioles) to permit diapedesis of specific leukocytes into the underlying parenchyma. Cells migrate toward inflammatory sites by following a chemotactic gradient. In a similar manner, blood-borne components carried in exudate accumulate outside of vascular beds, result in the delivery of serum factors essential for a functional response. The optional endpoint of this feedback reaction is resolution of tissue damage, and protection of the host from outside elements (pathogenic or physical). However, the inflammatory response may be caustic in and of itself; if it persists or triggers damaging adaptive immune function it may result in extended deleterious pathology.

Historically defined acute inflammation

The clinical consequences of inflammation are varied and unique to each organ or tissue. Why then ascribe a single condition of “inflammation” to the processes that lead to this damage? The combination of signs and symptoms observed following injury or illness are visible and consistent. The word “inflammation” is derived from the Latin “inflammare”, which literally means “to set on fire.” Greek literature suggests that ancient healers had an understanding of inflammatory response. Indeed, the first written definition of the condition was provided in the 1st century by Cornelius Celsus who noted four cardinal signs: *RUBOR ET TUMOR CUM CALORE ET DOLORE* (redness and swelling with heat and pain) (Rivas, 2010). It is now understood that redness occurs due to changes in localized blood flow (vasodilation); swelling occurs from influx of fluid and cells leaving blood vessels to enter tissue; heat is the result of increased blood arriving to areas of damage; and, pain results from released molecular mediators and edema (fluid accumulation) which increases pressure on, and activates, local nerves surrounding the damaged site. The concept that this response was more than tissue damage in response to injury was introduced in the 3rd century by Galen, whose description of “laudable pus” suggested that inflammation was beneficial and necessary for wound healing. The advent of microscopy in the late 19th century allowed for the identification of the cellular components of inflammation, further underscoring the role of infiltrating immune cells in the response. At this time, Virchow added a fifth “classical sign” of an inflammatory response—*FUNCIO LAESA* (loss of function) (Rather, 1971). It is this loss of tissue function that clinicians grapple with today.

A bird's eye view of the inflammatory process

Reaction to cellular injury can take multiple forms, due to initiating stimuli that either directly or indirectly manipulate responding cells in the area affected. The innate immune system is exquisitely sensitive to inflammatory triggering signals, and has the ability to quickly ramp up recognition upon real or perceived alterations in homeostasis (Kumar et al., 2020). It is now understood that infectious agents contain molecular motifs (e.g. danger signals) which trigger resting innate immune cells to initiate molecular activation of internal processes. However, it should be appreciated that physical agents, such as toxins and chemicals, can also activate similar responses. In fact, simple tearing of cellular membranes and subsequent release of phospholipids can result in vasoactive change (dilation or constriction) with the result being altered permeability for blood derived components to enter damaged areas (Galvão et al., 2018). Often, these signals arise from localized cell death due to ischemia, yet they can also be elicited by way of blunt physical trauma.

The initiation through stimuli induces further cellular responses, generally characterized as those mediated by locally residing innate cells (macrophages, dendritic cells or fibroblasts), and those recruited from vascular regions (neutrophils and specialized first responding lymphocytes such as natural killer cells). The cellular response is immediate, with explicit release of both preformed and induced substances from innate cell phenotypes. These effector factors (cytokines and chemokines) subsequently diffuse from the area of damage or danger to nearby blood vessels where they induce changes in endothelial cell membranes. A directed process of recruitment then occurs, based primarily on adhesion and migration properties of multiple circulating cell populations (Walzog and Gaetgens, 2000). Concurrently, fibrous matrix ladders assemble, providing a cellular thoroughfare for trafficking through subcapillary beds.

Overt changes in vascular permeability result in the delivery of a fluid exudate, which allows nutrients and oxygen to flow into areas of need. With respect to microorganisms, the sheer influx of fluid (edema) creates a safety buffer by diluting toxins. This vasodilation also permits fluids (serum) containing circulating antibodies, complement and acute phase proteins to accumulate within damaged tissue and submucosal spaces. The antibodies that are present combine with toxins, neutralizing their inherent destructive activities. Complement components, either by themselves or with the help of antibodies, directly lyse microorganisms, and coat them (opsonization) with breakdown products of the complement enzymatic cascade. This greatly assists in directed uptake and phagocytosis of encountered pathogens.

Fluid and cellular flow into damaged tissue is typically thought of as a one-way process, it should be noted that it is in fact dynamic. Signals from reactive components leave damaged sites and enter the blood stream with the purpose of systemic activation. Distant organs are affected, including those responsible for thermoregulation (e.g. the hypothalamic, pituitary and adrenal axis), and those responsible for production of additional enzymes and acute reactants (such as those produced by the liver). Over time, activated innate immune cells make their way to draining lymphatics and to lymph nodes where they condition lymphocytes for secondary hypersensitivity reactions. This step is critical for the adaptive second phase of response when lymphocytes are actively recruited to the area of inflammation; these lymphocytes have the capability to respond with exquisite specificity to non-host antigenic stimuli. It is this second wave of immune cells that are ultimately responsible for prolonged pathological consequences resulting from the initial stimuli. If the situation is limited in duration and scope, the acute reaction has minimal lasting effect. Resolution occurs with limited tissue reorganization. However, chronic persistence with repeated stimulation due to a contribution of innate and antigen-specific adaptive components can lead to progressive damage to tissue with lasting consequence and clinical scope.

Inflammation is thus a combination of desirable and non-desirable events, with these terms defined according to the underlying stimuli initiating reactivity. The clinical outcome is truly a balance between responses which benefit the health of the host, versus responses that lead to destructive pathology.

Inflammatory danger signals

PAMPs and DAMPs

Encounter with external stimuli can initiate the inflammatory response (Table 1), with the end result often dictating downstream (adaptive) immunity (Schenen and Medzhitov, 2011). Response to invading bacteria or viruses has evolved to combat their attempts at colonization. Basic phagocytic innate cells, macrophages and dendritic cells in particular, are hardwired to respond to motifs, or danger signals, present on and within microorganisms (Janeway, 1989; Akira et al., 2006). These signals are common pathogenic patterns (pathogen-associated molecular patterns; PAMPs) specific for non-eukaryotic cells, usually linked to pathogen survival. Examples of PAMPs include peptidoglycan and lipomannans, lipopolysaccharide and lipoteichoic acid, bacterial DNA, double-stranded RNA, and flagellin. Recognition occurs via unique surface or intracellular molecules expressed by phagocytes (e.g. mannose receptors, scavenger receptors, Toll-like receptors (TLRs), or C-type lectin receptors (CLRs)) which trigger subsequent endocytosis and/or internal activation (Brubaker et al., 2015).

Binding of the specific motifs to intracellular NOD-like receptors (NLRs), allows translation of encounter of the “danger” signal to initiate a protective proinflammatory response (Takeuchi and Akira, 2010), often via the assembly of an “inflammasome” (Dolasia et al., 2017; Platnich and Muruve, 2019; Triantafyllou, 2021). These are multicomponent molecular structures that link the bound NLR to the downstream activation of caspase-1; ultimately culminating in the production of small chemical mediators

Table 1 General inflammatory stimuli.

Type	Examples
Microbial infectious organisms	Pathogen associated molecular patterns Bacterial endo- and enterotoxins
Physical agents	Trauma Radiation Carcinogens
Irritants	Excessive temperature Foreign bodies (e.g. splinters, dirt) Corrosive chemicals Inhaled inorganic metals/dust Allergens
Tissue necrosis	Infarction and hypoxia Oxidative stressors

From Csencsits-Smith K and Actor JK (2018) *Translational Inflammation*. Elsevier: Philadelphia, PA. ISBN-13: 978-0128138328; ISBN-10: 0128138327.

(cytokines, chemokines) that work in concert to allow cells to communicate with each other and facilitate cross-talk. These molecules also lay the groundwork for destruction of the unwanted pathogen. Because of their varied nature, these mediators are quite pleiotropic and exert actions on multiple different cell types, often with overlapping and redundant functionality.

Realize that in addition to pathogens, danger signals presented by physical agents may also induce inflammation. Damage-associated molecular patterns (DAMPs) represent a second class of inflammatory inducing signals, usually host-derived biomolecules that initiate and perpetuate a noninfectious inflammatory response (Matzinger, 1998). In many cases, these “alarmins” are released by stressed tissue undergoing necrosis (Yang and Oppenheim, 2017; Rider et al., 2017). A class of molecules that should not be overlooked are those represented by foreign objects that trigger this type of stress inflammation. Irritants and corrosive chemicals (acids, alkalis, oxidizing agents) can cause cellular damage. This can also be seen in response to trauma, ultraviolet light, radiation, and even frostbite. In all of these examples, inflammation is elicited; the underlying mechanisms are initiated via damage to cellular membranes and/or apoptotic induced events. Released membrane phospholipids, combine with natural lipases to produce arachidonic acid, which then triggers prostaglandin and leukotriene production which in turn mediates vasoactive changes, endothelial cell permeability, and chemotaxis of polymorphonuclear cells. In fact, any cause of gross tissue necrosis, be it lack of oxygen or nutrients, inadequate blood flow due to infarction, or physical dysplasia, will initiate similar inflammatory episodes.

By definition, a toxin initiates a destructive process which often triggers inflammation. Bacterial toxins are biological virulence factors that prepare the host for colonization. A classic example is the lipopolysaccharide (LPS), a powerful endotoxin representing a portion of the outer membrane of Gram-negative bacteria. In contrast to endotoxins, bacterial exotoxins are soluble mediators released during bacterial cell lysis or destruction. A specific class of exotoxins, called enterotoxins, are especially toxic to the intestinal tract causing vomiting and diarrhea. Well defined toxins (neurotoxins, leukocidins or hemolysins) are classified in terms of the specific target cell or site affected.

The cellular players in the inflammatory response

To understand the development and control of the inflammatory response, it is imperative to understand the roles that each phenotypic cell plays in the process. A global chart for these cells is given in Table 2. Each individual cell type is further described to allow a context for activity in the overall process. These cells include the myeloid and lymphoid phenotypes, as well as fibroblasts, endothelial cells, and platelets. Many of these cell phenotypes exhibit great levels of functional plasticity, helping to shape the overall inflammatory environment (Galli et al., 2011).

Myeloid cells (monocyte/macrophages and polymorphonuclear cells)

Monocytes/macrophages

Monocytes and macrophages are directly involved in phagocytosis and intracellular killing of microorganisms (Bieber and Autenrieth, 2015). Macrophages are differentiated monocytes, which are one of the principal cells found to reside for long periods in the reticuloendothelial system. These monocytes/macrophages are highly adherent, motile and phagocytic; they marshal and regulate other cells of the immune system, such as T lymphocytes; they also serve as antigen processing-presenting cells. Upon

Table 2 Cells and general roles in inflammation.

<i>Phenotype</i>	<i>Morphology</i>	<i>Main effector function</i>	<i>Mediators of inflammation</i>
<i>Myeloid leukocytes</i>			
Neutrophil	PMN granulocyte	Phagocytosis and digestion of microbes; vaso-responsiveness	Leukotrienes, oxygen metabolites, complement activators, chemoattractants, defensins, hydrolytic enzymes
Eosinophil	PMN granulocyte	Immediate hypersensitivity (allergic) reactions; defense against helminths; vaso-responsiveness	Leukotrienes, cytokines, chemoattractants, peroxidases, major basic proteins
Basophil	PMN granulocyte	Immediate hypersensitivity (allergic) reactions; vaso-responsiveness	Chemoattractants, histamines, heparine, proteolytic enzymes, arachidonic acid, leukotrienes, prostaglandins
Mast cell			
Monocyte macrophage	Monocytic	Phagocytosis and digestion of microbes; antigen presentation to T cells; vascular permeability	Proinflammatory cytokines, anti-inflammatory cytokines, chemokines, vasoactive mediators, reactive oxygen metabolites
Dendritic cell	Monocytic	Antigen presentation to naïve T cells; initiation of adaptive responses	Proinflammatory cytokines; regulatory cytokines for T cell development
<i>Lymphoid leukocytes</i>			
B cell	Monocytic	Humoral immunity	Cytokines, immunoglobulins
Plasma cell	Monocytic	Terminally differentiated, antibody secreting B cell	Secreted immunoglobulins
T cell	Monocytic	Cell-mediated immunity (helper and cytotoxic); modulation of APC function (regulatory)	Regulatory cytokines, chemoattractants, cytotoxic factors (granzymes, perforins)
Natural killer T cell (NKT)	Monocytic (rare)	Cell-mediated immunity (lipids)	Cell-mediated immunity (lipids), cytokines, chemoattractants, cytotoxic factors
Natural killer cell (NK)	Monocytic	Innate response to microbial or infection; antibody dependent cell cytotoxicity	Cytotoxic factors (granzymes, perforins), cytokines
<i>Non-leukocytes</i>			
Platelet	A nuclear	Clotting and tissue repair	Prostaglandins, chemoattractants, coagulation factors
Fibroblast/keratinocyte	Elongated	Connective tissue, structural support	Chemoattractants, regulatory factors for PMN function
Endothelial cell	Monocytic	Vascular composition and blood fluidity; leukocyte trafficking; coagulation control	Vascular permeability, cellular adhesion factors, chemoattractants, platelet activating factor, prostaglandins, fibrinolytic constituents

From Csencsits-Smith K and Actor JK (2018) *Translational Inflammation*. Elsevier: Philadelphia, PA. ISBN-13: 978-0128138328; ISBN-10: 0128138327.

encountering different stimuli, monocytes differentiate into highly microbicidal macrophage (M1), or into immunosuppressive macrophage (M2) phenotypes (Arango Duque and Descoteaux, 2014; Arora et al., 2018). Macrophages are immediate responders during inflammation, changing phenotype in concert with immune evolution in response to threats and needs for homeostatic and surveillance tasks, as well as for tissue regeneration and repair (Lichtnekert et al., 2013). They bear functional pattern recognition receptors on their surface, as well as complement and antibody receptors, which make them key regulators for recognition of inflammatory stimuli. Upon activation, they secrete chemokines and cytokines that both regulate and attract other immune cells, as well as having strong impact on local vascular endothelium (Arango Duque and Descoteaux, 2014) as well as tissue repair and wound healing (Arora et al., 2018). Indeed, release of these inflammatory mediators strongly impacts the direction of subsequent immune function, both in a localized manner as well as systemically to affect tissues throughout the body. It should be stressed that while macrophages are critical in initial inflammatory responses, they also contribute to chronic responses. Finally, macrophages also regulate healing properties such as renewed vascularization of tissue, and wound closure (Hesketh et al., 2017).

Monocytic macrophages are called “macrophages” when they are in the connective tissue, spleen and lymph nodes. However, many submucosal macrophages have specific nomenclature, dependent upon tissue localization. For example, they are called Kupffer cells in the liver, Dust cells in the lung, Microglia in the central nervous system, osteoclasts in the bone, and Langerhans cells when found in the skin.

Dendritic cells

Dendritic cells (DCs) provide a link between innate and adaptive immunity by interacting with T cells in a manner to deliver strong signals for development of functional and memory responses (Yin et al., 2021). They represent an intriguing and diverse population (Steinman, 2012; Malissen et al., 2014) whose phenotypic control is under precise regulation (Hammer and Ma, 2013). They direct local responses during infection (Bieber and Autenrieth, 2015) and inflammation, as well as participate in the generation of matured responses post trafficking to lymph node tissues (Aguzzi et al., 2014; Chistiakov et al., 2014a). Immature DCs are called to

the site of inflammation via chemokines, in a complex signaling path which is dependent upon both physical location and necessity for specific triggering by other immune cells responding to the insult or assault (Chistiakov et al., 2014b). Dendritic cells recognize foreign agents and pathogens through a series of pattern recognition receptors (non-specific), and, are similar to macrophages in that they are able to present antigen to lymphocytes to direct maturation and immune functionality. They play critical roles within the skin (where they are referred to as Langerhan's cells) and have special properties to assist in wound healing and repair (Deckers et al., 2018; Gregorio et al., 2010).

Neutrophils

Neutrophils are the most highly abundant, motile, phagocytic leukocytes which are one of the first cells recruited to acute inflammatory sites. They are extremely important in development of acute and chronic inflammation (Pinegin et al., 2015; Jorch and Kubes, 2017). They ingest, kill, and digest pathogens, with their functions dependent upon special proteins, such as adherence molecules, or via biochemical pathways (respiratory burst). Neutrophils contain primary lysosomes which contain myeloperoxidase and acid hydrolases; they also contain secondary granules containing inflammatory mediators, such as lactoferrin, which can be released upon activation. Lactoferrin is especially important as a homeostatic modulator; lactoferrin can work both ends of the immunological spectrum to increase low response or dampen aggressive ones (Kruzel et al., 2017). Neutrophils express high levels of antibody receptors and complement receptors which allow increased phagocytosis of invading organisms. As a mechanism to help control the spread of intracellular pathogens, neutrophils are capable of deploying extra cellular traps (NETs) which consist of decondensed nucleosomes, neutrophil elastase, and myeloperoxidase (Brinkmann et al., 2004). Critical to the inflammatory process, neutrophils are recruited via specific chemokines (interleukin-8; CXCL8), through a dynamic process where they extravasate from endothelial lined vessels to enter tissue (Pick et al., 2013). Activation leads to respiratory burst producing reactive oxygen and nitrogen intermediates, and subsequently release primary and secondary granules containing proteases, phospholipases, elastases and collagenases (Kolaczowska and Kubes, 2013).

Eosinophils

Eosinophils defend against larger parasites and participate in hypersensitive reactions via cytotoxic events (Strandmark et al., 2016). Their cytotoxicity is mediated by large cytoplasmic granules, which contain eosinophilic basic and cationic proteins. These granules are somewhat unique and contain a dense filamentous core of major basic protein, forming structures known as crystalloids. The matrix of the granules contains lysosomal enzymes, and in particular has a high content of peroxidase, arylsulfatase, acid phosphatase, RNase and cathepsin. While the functionality of eosinophils are classic ascribed to parasitic infections, they also play a major role as responders in allergic reactivity to a variety of stimuli including pollen, and in some drug hypersensitivity reactions. These cells are known to phagocytose antigen-antibody complexes, which can also trigger responsiveness. They also have effects on leukotrienes, one major mediator of the inflammatory response.

Basophils/mast cells

Basophils, and their counterparts mast cells which reside in tissue spaces, produce cytokines that help defend against parasites (Gieseck 3rd et al., 2018; Symowski and Voehringer, 2017), and also cause allergic inflammation (Miyake and Karasuyama, 2017; Ryan et al., 2007). These cells display high affinity surface membrane receptors for IgE antibodies, and have many cytoplasmic granules containing heparin and histamine. The cells degranulate when cell-bound IgE antibodies are cross-linked by antigens, and produce low-molecular weight vasoactive mediators (e.g. histamine). Their granules contain high concentrations of heparin anticoagulant, and multiple vasodilating agents which cause increased vascular permeability. They also contain modulating agents such as slow reacting substance of anaphylaxis (a specific leukotriene), and serotonin. Basophils (and mast cells) typically have their IgE receptors completely saturated, so that when subsequently exposed to the corresponding antigen, they quickly release vasoactive substances leading to hypersensitive allergic reactions (defined as a "Type I" hypersensitivity). Of note, the mast cells respond aggressively during tissue trauma, upon which they release granules containing histamine, heparin, platelet-activating factor, and other substances.

Natural killer cells

NK cells are large granular "innate" lymphocytes that nonspecifically kill certain types of tumor cells and virus-infected cells (Ignacio et al., 2017; Mujal et al., 2021), with recent emerging data to indicate properties that assist during bacterial infections as well (Guo et al., 2018). They are a critical component in multiple facets of inflammation, including being participants in chronic inflammatory disorders (Parisi et al., 2017). NK cells share many surface molecules with T lymphocytes. These circulating large granular lymphocytes are able to kill "self" in the absence of antigen-specific receptors. NK cells are especially effective against virus-infected cells, and keep the expansion of virus in check until the adaptive immune response develops. In this regard, they also secrete interferon-gamma, which is an effective immunoregulator. NK cells can also kill via antibody-dependent cellular cytotoxic mechanisms (ADCC) via their receptors for the constant portion of antibodies (Fc receptors). NK cells express a large number of receptors that deliver either activating or inhibitory signals, and the relative balance of these signals controls NK cell activity.

Endothelial cells

Specialized epithelial cells play a key role in both acute and chronic inflammation by facilitating the transfer of fluid and cells from the blood into the local tissue (Sturtzel, 2017; Greven et al., 2018). In response to chemical mediators such as histamine, endothelial cells contract and the intercellular junctions separate, allowing for rapid and transient vascular leakage near the area of inflammation. Signals from pro-inflammatory cytokines including tumor necrosis factor (TNF) and interleukin-1 (IL-1) trigger endothelial cells to express adhesion molecules on their cell surface, which facilitate binding and subsequent extravasation of leukocytes from the blood into surrounding tissue (Pick et al., 2013). Vascular endothelial cells also play an important role in tissue repair by participating in angiogenesis. In response to vascular endothelial growth factor (VEGF), endothelial cells can migrate, proliferate, and mature in newly formed blood vessels. Endothelial cells secrete multiple factors which affect tissue repair (Godo and Shimokawa, 2017), and play a key role in the clotting cascade. Specifically, they respond to the presence of activated thrombin by releasing tissue-type plasminogen activator (t-PA) as well as plasminogen activator inhibitors. Recent advances have begun to describe additional activities for endothelial cells in overall homeostasis and vascular remodeling events during inflammatory disease (Sachdev and Lotze, 2017) and chronic fibrosis (Specia et al., 2012; Duffield et al., 2013).

Fibroblasts

Fibroblasts are critical within the inflammatory process because of their ability to modify connective tissue and parenchymal structure (Jordana et al., 1994). They are readily found as resident cells in submucosal loose connective tissue, and contribute to both innate and adaptive inflammatory functions (Mack, 2018; Richards, 2017). They produce collagen that makes up collagen fibers which are important components of tissues requiring rigidity, flexibility, and strength. A critical product made by fibroblasts is fibronectin, which mediates normal cell adhesion and migration. Indeed, the extracellular matrix proteins made by fibroblasts certainly influence the shape, movement and state of activation of inflammatory cells in localized tissue. It should be noted that many of the components involved in the production of extracellular matrix are active in regulation of the inflammatory process, and play substantial roles in homing of inflammatory cells to certain sites. Finally, differentiated subsets are known to produce neuropeptides, lipid mediators, cytokines and growth factors, which all actively contribute to regulation of inflammatory events that culminate in fibrosis (Duffield et al., 2013; Wynn, 2008).

Platelets

The process of coagulation and repair of injured tissue results in multiple pathways involved in development and control of inflammation. Platelets are integrally involved in thrombosis (bleeding cessation), and contain potent immune effector molecules (Carestia et al., 2016; Jenne and Kubes, 2015). Platelets aggregate on damaged endothelium and exposed collagen, releasing contents of alpha and dense granules which actively promote the coagulation cascade. Multiple plasma factors correlate and connect to form a blood clot, with ultimate formation of a platelet plug referred to as "primary hemostasis." The entire coagulation pathway, both involving the kinin and clotting cascades, results in fibrin degradation, which heavily influences the activation and alteration of complement factors. Released complement factors, specifically complement C3a and C5a, are powerful contributors as chemotactic and anaphylactic agents to the inflammatory response. Platelets are also integral in inducing production of Neutrophil Extracellular Traps (NETs).

Lymphoid leukocytes

The lymphoid leukocytes are considered secondary responders to inflammation, contributing to both acute and chronic reactivity (Hwang and Actor, 2014). As such, they are included within this discussion, albeit in a limited overview. In many cases they function only after pre-exposure to external antigen or developed reactivity to self-antigen. They must work in concert with antigen presenting phagocytic cells, and do so in a specific antigen receptor based manner. Because of their unique ability to recognize antigen, these types of cells fall into the acquired immune category, which includes the B lymphocytes and the T lymphocytes. The B lymphocytes secrete antibodies. The T lymphocytes operate in a supervising role to mediate cellular and humoral immunity. A third group, the NK cells (mentioned above), work in concert with antibodies in defense against viral agents. Finally, innate lymphoid cells, a relatively new-comer to the appreciation of inflammatory processes, should also be recognized as influencers in the acute inflammatory process (Kumar, 2021).

B lymphocytes

The majority of the effects of B lymphocytes in inflammation are caused by their differentiation into antibody-secreting plasma cells (Lebien and Tedder, 2008). The role of antibodies is outlined in detail later in this chapter. Importantly, memory B cells are more reactive to antigen stimulation, and can provide antigen-independent help for T cells that drive adaptive inflammatory responses (Good et al., 2009). Recent evidence points to a significant role for specialized subsets of B lymphocytes in the modulation of inflammatory response. The regulatory B cell subset produces IL-10 that results in down-regulation of MHC on APC cell surface.

On the other side of the inflammatory coin are pro-inflammatory B cells that produce IL-6. CD5 + B1 cells may represent an inherent regulatory population of cells that produce “natural” IgM and IgG autoantibodies that are anti-idiotypic in nature that may keep autoimmune response under control.

T lymphocytes

The T lymphocytes are the true ringleaders of the adaptive response. Different subsets control different functions (Hwang and Actor, 2014; O’shea and Paul, 2010; Nakayamada et al., 2012). Some help B cells produce antibodies. Others help the myeloid cells more efficiently destroy pathogens, and thus elevate the inflammatory response in a localized and directed manner which is dictated by unique stimulating antigens at the root of the response. Some preferentially function to kill viral infected cells or tumor cell targets. Finally, some function as regulators, conferring immune tolerance or establishing limits on responsiveness.

The T lymphocytes are critical in inflammatory responses that involve specific recognition of antigens, small shapes which are presented via major histocompatibility markers on antigen presenting cells. As such, they do not directly initiate the inflammatory response, but rather direct the level of responsiveness after the antigen has been processed. With that said, they are critically important in both acute and chronic inflammation. The ability to recognize specific foreign antigenic stimuli places these cell phenotypes in a directive role to regulate pathological damage during infection; when the stimuli is “self,” they function to control autoimmune reactivity. The involvement of T lymphocytes in development of pathology is the definition of a classical adaptive inflammatory hypersensitive response (Cosmi et al., 2014). While a complete and exhaustive role of specific T cell subsets is beyond the scope of this discussion, their functional presence in adaptive inflammation leads to multiple distinct disease states. These cells are indeed critical in the maturation of responses forming the basis of the type IV hypersensitivities.

Chemical mediators of inflammation

The chemical mediators of inflammation have been extensively studied (Griffith et al., 2014). These factors were historically identified as molecules which are capable of inducing edema upon injection, stimulating smooth muscle contraction, or altering blood pressure following administration. These substances can act via direct stimulation of cell surface receptors (e.g. histamine) or function as plasma derived factors that cause direct tissue damage (e.g. complement). Alternatively, they may function as chemotactic agents to attract specific cell phenotypes to areas of inflammatory response (e.g. chemokines; arachidonic acid metabolites). Some of the major chemical mediators of inflammation are listed in Table 3.

Many of these molecules represent systems that are interrelated (Kumar et al., 2017). For example, the complement components (lytic, vasoactive, chemotactic) are linked to the kinin pathway (vasoactive mediation, pain) which is linked to the fibrinolytic system (clotting, vasoactive) (Kaplan et al., 1981; Kaplan and Joseph, 2014). Molecules effective at coagulation and repair work to direct the clotting cascade and the production of fibrin. Plasma serine proteases function to produce kinins, which mediate vascular permeability and pain. Proteins and enzymes released by platelets help to further drive and direct the response. Keep in mind that these factors initiate molecular changes that are extremely beneficial from an immunological standpoint. Clotting and formation of a fibrin matrix impedes movement of microorganisms. In addition, breakdown products generated in the cascading events also attract and activate incoming leukocytes.

Neurogenic inflammation should be regarded as protective mechanism to buffer trauma (Corrigan et al., 2016). Molecules associated with neurogenic inflammation include substance P (SP) and calcitonin gene-related peptide (CGRP), as well as neurokinin A, neuropeptide Y and vasoactive intestinal polypeptide (VIP) (Brain, 1997; Luger, 2002; Duan et al., 2017). These agents are under investigation as strong modulators of the inflammatory response.

Role of antibodies in inflammation

A major benefit of the influx of fluid is the direct delivery of antibodies. The circulating plasma is filled with relatively high levels of antibodies that, as a group, have the ability to recognize just about any shape or form of antigen. Depending on prior exposure or positive vaccination status, there may also be an abundance of specific antibodies reactive to antigenic features present on destructive pathogens.

Antibody entry to the area confers multiple functions, the most critical of which resides within the variable region of the antibody molecule that can recognize unique shapes and forms, with a specific and unique binding site to allow direct interaction with a pathogen or to pathogen-derived proteins (Cohen and Milstein, 1967). Antibodies recognizing toxins and deleterious pathogenic factors can inhibit and/or neutralize their toxic properties. Direct binding to the pathogen also results in inhibition of organism movement. In the case of viruses, antibodies can inhibit infection of host cells by blocking attachment and adhesion. Antibodies can also limit direct expansion of bacterial organisms; for example, recognition of multiple regions on the microorganism can result in a latticework precipitate which inhibits movement and promotes organism clearance.

The constant region of the antibody molecule has a constant structure which confers biological function that is critical for initiation of the inflammatory response (Franklin, 1975; Schroeder and Cavacini, 2010). Innate phagocytic cells contain receptors on their surface for this constant portion of the antibody. This assists the phagocyte in targeted pathogen engulfment and subsequent intracellular destruction. The term for coating the organism with antibodies is opsonization.

Table 3 General mediators of inflammation.

<i>Molecules</i>	<i>Effects</i>	<i>Source</i>
<i>Vasoactive amines</i>		
Histamine	Vasodilation	Preformed, released by local cells
Serotonin		
<i>Neuropeptides</i>		
CGRP	Transmit pain	Secreted by nerve fibers
Substance P	Regulate vessel tone	
VIP	Modulate vascular permeability	
<i>Plasma proteases</i>		
Bradykinin	Vasodilation Increased vascular permeability Pain	Synthesized in liver, circulate in plasma, cleaved to active forms downstream of Factor XII activation
Thrombin	Vasodilation Increased vascular permeability Chemotaxis	
C3a	Vasodilation Increased vascular permeability Increased phagocytosis, chemotaxis	
C5a	Vasodilation Increased vascular permeability Leukocyte activation and chemotaxis	
<i>Arachadonic acid metabolites</i>		
Prostaglandins	Vasodilation Pain	Short range hormones produced by local cells; derived from membrane phospholipids; produced via the cyclooxygenase or lipoxygenase pathways
Leukotrienes	Increased vascular permeability Leukocyte activation and chemotaxis	
Lipoxins	Leukocyte activation and chemotaxis	
<i>Cytokines/chemokines</i>		
IL-1, TNF α , IL-6	Vasodilation	Short range molecules produced by local cells (macrophages, dendritic cells, lymphocytes)
IL-8 (CXCL8)	Leukocyte activation and chemotaxis	
Eotaxins, IL-5	Eosinophil attractant	
Interferons	Immune cellular activation	
TGF- β , VEGF	Tissue repair	
<i>Other</i>		
Platelet activating factor	Platelet aggregation, vasoconstriction and vasodilation, vascular permeability, increases leukocyte adhesion, increases oxidative burst	Produced by platelets, endothelial cells and leukocytes
Reactive oxygen species	Oxygen derived free radicals, increased vascular permeability, smooth muscle control	
C-reactive protein	Binds phosphorylcholine on microorganisms' enhances macrophage phagocytosis	Produced in the liver; general marker for inflammation
Lactoferrin	Immune modulation to maintain inflammatory homeostasis	Produced by neutrophils; exocrine secretions; present/secreted in high concentrations on mucosal surfaces

From Csencsits-Smith K and Actor JK (2018) *Translational Inflammation*. Elsevier: Philadelphia, PA. ISBN-13: 978-0128138328; ISBN-10: 0128138327.

Complement

Overall, complement and its related components exert multiple biological functions that are critical components of inflammation, including activation and regulation of both innate and adaptive immune functions (Ricklin and Lambris, 2013; Hajishengallis et al., 2017). It has been well accepted for decades that tissue damage caused by both immunological mechanisms as well as non-immunological trauma can initiate surface dependent pathways of coagulation, fibrinolysis, and kinin formation (Kaplan et al., 1981). Complement is important in direct cytolysis of invading organisms, in coating organisms to enhance phagocytosis for targeted destruction, and as a specific director of leukocyte chemotaxis (Noris and Remuzzi, 2013). Complement is a term that originally referred to the heat labile factor in serum that causes immune cytolysis. It comprises at least 30 distinct serum proteins that affect multiple biological functions in a tightly regulated manner. These components are inert when normally present in serum, however, a “cascade” of events occur when these molecules interact with signaling agents. Activation of complement enzymes results in subsequent cleavage of proteins to yield specific polypeptide fragments with short-lived enzymatic functions related to inflammation. In essence, proteolytic degradation of the complement components drives many aspects of immunity.

Different pathways exist to initiate complement activation. One pathway, referred to as the Classical Pathway, utilizes antibodies as the initiating signal. Antibody opsonization (coating) of organisms targets them for attack. The “first” complement component (called C1) interacts with the constant portion of specific classes of antibody bound to the surface of the bacteria. This initiates a cascading series of enzymatic reactions whereby a complex structure is built upon the bacterial cell surface. Synthesis of this structure culminates in a pore channel, called a membrane attack complex, which causes osmotic lysis of the pathogen or infected cell. Two additional pathways of complement activation, the Alternate Pathway and the Lectin Pathway, also function to allow direct lysis of microorganisms in the absence of antibodies. In these enzymatic cascades, deposition of complement components directly to pathogens occurs via recognition of bacterial sugars and lipids, with eventual pore channel assembly on the organism surface. Furthermore, breakdown of components during the cascading enzymatic process creates smaller molecules, opsonins, which remain deposited on the pathogens. These opsonins act as molecular beacons, allowing interaction with receptors on macrophages, monocytes, and neutrophils to enhance phagocytosis and elevate mechanisms of targeted organism destruction.

One of the most prevalent byproducts of the complement enzymatic cascade is the production of molecules with the ability to directly affect migration of leukocytes (Sarma and Ward, 2011). Proteolytic degradation of complement components releases leukocyte chemotactic factors referred to as anaphylatoxins. For example, breakdown products of complement component C3 and C5 produces responses triggering smooth muscle contraction and increased vascular permeability, as well as chemotactic functions. C3 is chemotactic for eosinophils. Proteolytic digestion of component C5 produces a much more potent chemokine, attracting neutrophils, monocytes and macrophages, and eosinophils. Another major property of the enzymatic cascade is the production of factors that activate those incoming cells. For example, interaction of components C3a, C4a or C5a with mast cells and basophils leads to release of histamine, serotonin, and other vasoactive amines which further drive vascular permeability. One can readily see that byproducts of the complement cascade can directly influence local inflammatory responses. Indeed, directed targeting of these products may well dictate future therapeutic modalities to control both acute and chronic inflammatory responses (Morgan and Harris, 2015). Finally, it is important to consider that recent investigations now identify multiple roles for complement outside of the cytolytic cascade; there are identified roles for phagocytic activities and subsequent cytokine production by antigen presenting cells, and functionality in the T-lymphocyte maturation process (Thielens et al., 2017; Lu and Kishore, 2017; West et al., 2018).

Consequences of hypersensitive inflammation

So far, the concept of inflammation has been presented as an action in response to disease. Yet it should be stressed that inflammation may be the cause of disease as well (Hwang and Actor, 2015). Inflammation is the basis for all hypersensitive reactions, defined as an immune response that leads to elements of host pathology. The hypersensitivity reactions fall readily into four established subgroups characterized on their mechanisms and the ability to passively transfer response through antibodies or through T lymphocytes. These responses include “inappropriate” antigenic response, excessive magnitude of response, prolonged duration of response, and innocent bystander effect reactions leading to tissue damage. The hypersensitivities, whether they be acute or chronic in nature, can lead to clinical inflammation (Table 4).

Hypersensitivities

Molecular pathways for each hypersensitivity class have been detailed, according to classifications defined by Gell and Coombs (1963), although there is a certain amount of mechanistic overlap between groups (Abbas et al., 2020; Actor, 2012), and plenty of room for interpretation over the past 50+ years that “hypersensitivities” have been described (Descotes and Choquet-Kastylevsky, 2001). Type I hypersensitivity (also called immediate or allergic hypersensitivity) is due to aberrant production and activity of IgE against normally nonpathogenic antigens (commonly called allergens). The response is relatively quick (15–30 min post exposure). The IgE binds to mast cells via high affinity IgE receptors; antigen exposure results in crosslinking of mast cell bound IgE with release of preformed mediators (e.g. histamine, leukotrienes, etc.). Type II hypersensitivity is dependent on antibody directed against cell membrane-associated antigen that results in cytolysis. This reaction occurs minutes to hours after contact with the antigen. The mechanism may involve complement (cytotoxic antibody) or effector lymphocytes that bind to target cell-associated antibody and effect cytolysis via a complement independent pathway (Antibody dependent cellular cytotoxicity, ADCC). Type III hypersensitivity results from soluble antigen-antibody immune complexes that activate complement. Accordingly, reactions take time to develop (up to 8 h). The antigens may be self or foreign (i.e. microbial); the byproducts of complement activation (C3a, C5a) are chemotaxins for acute inflammatory cells. Type IV hypersensitivity (also called Delayed Type Hypersensitivity, DTH) involves macrophage-T cell-antigen interactions that regulate activation and cytokine secretion. These reactions develop over the course of 2–3 days, thus they are described as “delayed-type” in nature. Diseases such as tuberculosis, leprosy and sarcoidosis as well as contact dermatitis are all clinical examples where the tissue injury is primarily due to the vigorous inflammatory immune response rather than the inciting pathogen itself (Hwang and Actor, 2015).

Fortunately, most acute inflammation is self-limiting with resolution of immediate effects that result in normal homeostasis of tissue regions involved. There may be residual scarring or fibrosis related to the healing process post inflammation. When considering chronic inflammation, the level of tissue damage is related in part to length of response, clearance of reactive components, and overall proliferative and regenerative capacity of the parenchyma affected.

Table 4 Clinical consequences of acute and chronic inflammation due to hypersensitivities.

Type	Classification	Clinical examples
I	Allergic (immediate)	• Anaphylaxis • Allergic rhinoconjunctivitis • Allergy to penicillin, bee sting, food or pollen
II	Cytotoxic	• Autoimmune hemolytic anemia • Myasthenia gravis (antibodies to acetylcholine receptors) • Granulocytopenia or thrombocytopenia • Goodpasture's nephritis or pemphigus
III	Immune complex	• Arthus reaction • Systemic lupus erythematosus; lupus nephritis • Rheumatoid arthritis • Polyarteritis
IV	Delayed type (DTH)	• Tuberculin (Mantoux) reaction • Poison ivy • Tuberculosis, leprosy, toxoplasmosis, leishmaniasis • Blastomycosis, histoplasmosis

From Csencsits-Smith K and Actor JK (2018) *Translational Inflammation*. Elsevier: Philadelphia, PA. ISBN-13: 978-0128138328; ISBN-10: 0128138327.

Conclusions

Multiple events are involved in normal physiology of tissue maintenance. In reality there is a balance between factors necessary for response to damage and subsequent tissue repair. Indeed, it is critical to view inflammation as a homeostatic fulcrum, integral in both sides of the equation to allow flexibility in function in normal homeostasis. Most often, inflammation is beneficial to the host, but dysregulation or unbalanced response may also cause tissue damage. Understanding how pathways control this balance will be critical for therapeutic intervention and development of translational aspects to treat disease and disorders.

The focus of this overview defines a perspective of the inflammatory response in a way that permits discussion of its control as a therapeutic mechanism to combat disease. Understanding the role of inflammation in various disease states allows those in medical and related theoretical fields to gain insights into the inflammatory response. Thus, knowledge of the inflammatory pathways, and defining elements involved in those pathways as they relate to disease development, furthers understanding on how inflammation impacts manifestation of clinical disorders.

Definition

In a normal condition, the immune system is designed to defend against hazardous organisms without causing severe damage to the human body. However, in hypersensitivity disorders, the immune response is either exaggerated or inappropriate, which leads to tissue damage.

Etiology

Three major mechanisms by which hypersensitivity responses are mediated are as follow.

Excessive response to micro-organisms

Mounting an exaggerated response to a microbe or upon exposure to a persistent antigen can result in various types of tissue damage. For instance, antibodies produced against a specific antigen may bind with their ligands and form immune complexes (ICs), which can then be trapped in tissues, causing inflammation and tissue injury. Additionally, in tuberculosis, an example of a persistent antigen, an excessive T-cell mediated immune response gives rise to inflammation, which is a driving force in formation of inflammatory structures called “granuloma” (Abul et al., 2017a).

Autoimmunity

Self-tolerance is a process leading to the unresponsiveness of the immune system to self-antigens, molecules, and cells (Wang et al., 2014). The failure of self-tolerance can lead to autoimmune diseases. Autoimmune diseases are chronic illnesses with a growing prevalence of 3–5% (Lerner et al., 2015). These diseases are most common among women, and the age of onset is usually between the 20s–40s (Wang et al., 2015).

Inappropriate response to innocuous antigens

In a healthy status, the immune system usually does not respond to harmless environmental antigens such as pollen, animal dander, dust mites, drugs, milk, egg, fish, soybeans, peanuts, latex, tree nuts, and wheat. However, in 20–30% of the world population, these antigens initiate a damaging immune response (Pawankar et al., 2012). They can trigger production of immunoglobulin (Ig)E and mast cell degranulation, resulting in allergic reactions (Valenta et al., 2018). Skin contact of these antigens can also activate T-cells, leading to increased secretion of pro-inflammatory cytokines (Ho et al., 2015).

Classification

Hypersensitivity disorders can be divided into four major groups; namely, immediate (type I) hypersensitivity, antibody-mediated (type II) hypersensitivity, IC-mediated (type III) hypersensitivity, and delayed-type hypersensitivity (type IV). More than 40 years ago, Philip Gell and Robin Coombs coined this classification, which is still widely used (Cell and Coombs, 1963). Table 1 illustrates the different types of hypersensitivity and corresponding diseases.

Type I (immediate) hypersensitivity

Introduction

Type I hypersensitivity, the most prevalent hypersensitivity disorder, is also the most common immune disease, generally known as allergy or atopy. Type I hypersensitivity can manifest in less than 24 h; therefore, it is also called immediate hypersensitivity (Justiz Vaillant AA, 2019). In patients suffering from this disorder, excessive production of IgE in response to harmless antigens can cause a wide variety of symptoms ranging from moderate reactions, such as itching, to severe responses, such as death (Sheldon et al., 2014). T-helper 2 cells, IgE, mast cells, and eosinophils are the key role players in type I hypersensitivity (Delves et al., 2017b).

Mechanism

We can divide the underlying mechanism of type I hypersensitivity into two stages: sensitization stage and effector stage.

Sensitization stage

Subsequent to exposure to an allergen, a cascade of events leads to sensitization of the immune cells to the particular antigen. At first, dendritic cells residing in epithelia process the antigen, transfer it to lymph nodes and present it to CD4+ naive T-helper cells (Zhu, 2015). Then these cells differentiate into mature T-helper 2 cells and release cytokines; namely, IL-4, IL-5, and IL-13. These cytokines play several roles in the pathophysiology of allergy. For instance, IL-5 results in eosinophil activation, and IL-13 induces mucus production by epithelial cells (Wynn, 2015). Class switching of the B cells to IgE production is the most prominent effect of these cytokines. CD40 ligand, which is expressed by the activated T cells, is the other crucial factor in the class switching of B cells.

A large proportion of the IgE produced as a result of B cell class switching enters the circulation and binds with the high-affinity Immunoglobulin E receptor (FcεRI) of basophils and mast cells while the rest of IgE may act locally. Normally, the concentration of circulatory IgE is less than 1 µg/mL. However, this concentration soars in allergic reactions (Abul et al., 2017b). The remaining IgE in the region where the allergen penetrated binds to the allergen or cross-reacts with the FcεRI of mast cells in the tissue (Li et al., 2019). Subsequent to the linkage of IgE and FcεRI, mast cells are sensitized to the allergen and will react to the next exposure (Ishizaka and Ishizaka, 2016).

Table 1 Different types of hypersensitivity and their correspondent diseases.

<i>Hypersensitivity type</i>	<i>Characteristic feature</i>	<i>Diseases</i>
Type I hypersensitivity	Immediate	● Anaphylaxis ● Asthma ● Allergic rhinitis ● Atopic eczema ● Urticaria ● Food allergy
Type II hypersensitivity	Antibody-mediated	Cellular destruction ● Autoimmune hemolytic anemia ● Immune thrombocytopenia ● Hemolytic disease of the newborn Inflammation ● Rheumatoid fever ● Good pasture syndrome ● Rheumatic fever ● Pernicious anemia ● Pemphigus(ref:primer) Cellular dysfunction ● Myasthenia gravis ● Graves' disease
Type III hypersensitivity	Immune complex-mediated	● Systemic lupus erythematosus ● Post-streptococcal glomerulonephritis ● Polyarthritis nodosa ● Serum sickness
Type IV hypersensitivity	Cell-mediated and delayed	● Contact dermatitis ● Hashimoto thyroiditis ● Multiple sclerosis (MS) ● Rheumatoid arthritis (RA) ● Type1 diabetes ● Guillain-Barre syndrome ● Celiac disease ● Crohn's disease ● Graft-versus-host disease (GVHD) ● Autoimmune myocarditis

Effector stage

When the immune system becomes sensitized to the allergen, the subsequent exposures trigger the effector stage. The primary immune cells involved in this stage are mast cells, basophils, eosinophils, and T-helper 2 cells. This stage can be divided into immediate and late-phase responses, which are explained in the following lines.

● Immediate phase response

Mast cells are the principal elements of the immediate response. Upon the subsequent exposures, allergens cross-link with several IgE molecules attached to FCεR1s on the mast cells which leads to their activation (Renke et al., 2019). After activation, mast cells release their intracellular granules, which were previously formed and stored (Amin, 2012). The degranulation is triggered by an increased Ca^{2+} influx (Borriello et al., 2017). The granules contain histamine, serotonin, chemotactic factors, proteoglycans, amines, cytokines, and enzymes such as lysosomal hydrolases and proteases (Wernersson and Pejler, 2014). Histamine and serotonin can cause vasodilation and bronchial smooth muscle cell contraction. Histamine can also increase vascular permeability, increase mucus production (in asthma), and affect sensory nerves, which may lead to itching and eczema or may cause sneezing (in hay fever) (Thangam et al., 2018; Mygind, 2014; Yang and Kim, 2019; Tak Mak and Jett, 2014).

After degranulation, the reaction of mast cells is continued by rapid de novo synthesis of lipid mediators and cytokines (Gonzalez-De-Olano and Alvarez-Twose, 2018). Lipid mediators, including prostaglandin D_2 ; leukotrienes C_4 , D_4 , and E_4 ; and platelet-activating factor (PAF), are derived from arachidonic acid (Fanning and Boyce, 2013). Prostaglandins and PAF promote aggregation of platelets and contraction of respiratory smooth muscles (Tak Mak and Jett, 2014). Moreover, PAF is known to play a key role in development of nasal congestion in hay fever (Munoz-Cano et al., 2019). Leukotrienes can cause vasodilation, eosinophil recruitment, increased vascular permeability, and mucus production in addition to bronchoconstriction (Jo-Watanabe et al., 2019). Additionally, the cytokines are also responsible for initiation of the inflammatory response (Ngoc et al., 2005).

● Late-phase response

The late-phase response takes place approximately 3–5 hours after the exposure to the allergen and lasts for roughly 24 hours. T-helper 2 cells, eosinophils, neutrophils, basophils, and macrophages are the involved cells in this stage (Tak Mak and Jett, 2014).

Due to the chemotactic factors produced during the immediate response, the immune cells transfer from the circulation to the site of allergy (Tak Mak and Jett, 2014). These cells can produce inflammatory mediators causing tissue injury. For instance, eosinophils, one of the major effector cells in this step, secrete (1) enzymes, which can be toxic to the tissue; (2) leukotrienes, which can lead to bronchoconstriction, increased mucus production and vascular permeability; and (3) cytokines, which are chemotactic factors and can trigger eosinophil production (Fulkerson and Rothenberg, 2013; Abul et al., 2017b).

Examples of diseases caused by type I hypersensitivity

Anaphylaxis

Anaphylaxis is defined as “a serious, generalized or systemic, allergic or hypersensitivity reaction that can be life-threatening or fatal” by the International consensus on (ICON) anaphylaxis (Simons et al., 2014). The prevalence of this rapid-onset hypersensitivity reaction is estimated to be 0.3–5.1% (Tejedor Alonso et al., 2015). Except for idiopathic cases, it can be caused by drugs, insect venoms, foods, biological agents, and human seminal fluid (Lieberman et al., 2015). The rapid and extensive releases of vasodilators and inflammatory mediators such as histamine, PAF, and cysteinyl leukotrienes (CysLTs) by mast cells and basophils can have detrimental effects on the respiratory, cardiovascular, digestive systems and the skin. The most common signs and symptoms of the disease include dyspnea, wheeze, hypotension, tachycardia, nausea, abdominal pain, urticaria, cutaneous angioedema, and flushing (Reber et al., 2017). The immediate management of anaphylaxis includes removal of the triggering factor, injection of epinephrine, using supplemental oxygen, and administering intravenous fluids to resuscitate the volume (Brown, 2005; Simons, 2004). Interestingly, omalizumab, an anti-IgE antibody, is found to reduce the risks of anaphylaxis (Brosby-Olsen et al., 2018).

Food allergy

Food allergy is an inappropriate and potentially dangerous response of the immune system to certain innocuous protein antigens in food. With an estimated prevalence of 6–8% and less than 3%, respectively, food allergy is more common among children compared to adults (Loh and Tang, 2018). It occurs both dependent and independent of IgE. However, IgE-mediated reactions are more common (Sampson, 2016). In IgE-mediated food allergy, exposure to minimum amounts of specific foods can lead to a soar in IgE production, leading to local and/or systemic symptoms (Renz et al., 2018). While the foods triggering food allergy may vary in different regions, egg, milk, and wheat are the most common triggers (Yu et al., 2016). The symptoms of food allergy include involvement of the skin and the mucosal membrane (causing urticaria, erythema, angioedema, and pruritus), the respiratory system (causing hoarseness, dysphagia, coughing, wheezing, and dyspnea), the digestive system (causing nausea, diarrhea, vomiting, and abdominal pain), the cardiovascular system (causing decreased blood pressure and arrhythmia), and the nervous system (causing weakness and headache) (Ebisawa et al., 2017). In severe cases, it can also lead to anaphylaxis (Devdas et al., 2018). Currently, there is no optimum treatment available for food allergy. Avoidance is the recommended management. Additionally, to alleviate the systemic and localized allergic reactions, adrenalin, and antihistamines can be used respectively (Boyce et al., 2011; Iweala et al., 2018).

Asthma

Asthma is a chronic heterogeneous condition causing inflammation of airways which leads to tightening of bronchial tubes and difficulty in breathing (Mims, 2015). Asthma, with an estimated global prevalence of 4.3%, is more common in the developed countries (Loftus and Wise, 2016; To et al., 2012). Environmental, epigenetic, and genetic factors are involved in its pathogenesis. Notably, the underlying mechanism of asthma can be widely varied (Russell and Brightling, 2017; Portelli et al., 2015). For instance, paucigranulocytic asthma is associated with increased number and activity of eosinophils, neutrophils, and inflammatory cells. Asthma can also either result from allergy or not (Papi et al., 2018). Fig. 1 summarizes different immunopathologies of asthma. Immune responses can cause remodeling of mucosa (epithelial hyperplasia and metaplasia of goblet cells) and submucosa (hypertrophy of smooth muscle and enlargement of mucous gland). These changes give rise to bronchial obstruction and excess production of mucous (Holgate et al., 2015). Shortness of breath, wheeze, cough, and chest pain are the most common manifestations of asthma. The diagnosis can be established when these clinical features are accompanied by evidence of variable airflow restriction, which is usually provided by spirometry (Brigham and West, 2015). Management of asthma, a key factor of which is avoiding triggers of exacerbation, aims to reduce both current impairment and future risks. While treatment options vary in different patients, inhaled and oral corticosteroids, short and long-acting β_2 -receptor agonists, and leukotriene receptor antagonists are used in a stepwise approach in asthma management (Papi et al., 2018).

Type II (antibody-mediated) hypersensitivity

Introduction

Type II hypersensitivity is mediated by antibodies, which are typically IgG or sometimes IgM, directed to endogenous antigens or exogenous antigens, such as penicillin. Type II hypersensitivity, which is the underlying mechanism of several autoimmune disorders, is usually limited to one type of tissues or organ. Binding of these antibodies with their antigens can result in cytotoxicity (mainly mediated by components of the complement system) or abnormal cell function without cytotoxicity.

Fig. 1 Immune Mechanisms involved in the pathophysiology of asthma: Five distinctive patterns may be seen in asthma: 1- *Allergic eosinophilic inflammation*, in which after encountering an allergen, activation of dendritic cells results in production of IL4, IL-5, and IL-13 from T-helper2 lymphocytes. The produced IL-5 promotes maturation of eosinophils, and the produced IL-4 leads to antibody class-switching of B cells to IgE, which stimulates mast cells. 2- *Non-allergic eosinophilic inflammation*, in which subsequent to epithelial injury, the epithelium promotes release of TSLP, IL-25, and IL-33. In response to these mediators and PGD₂, ILC2 releases IL-5 and IL-13. 3- *Non eosinophilic asthma*, which can be seen in some patients; however, its mechanism is not fully elucidated. 4- *Neutrophilic inflammation*, in which the dominance of neutrophils can stem from bacterial colonization or usage of corticosteroids (suppressing type 2 immune responses and increasing neutrophil survival). In this pattern, cytokines released from T-helper1 lymphocytes, T-helper17 lymphocytes, or ILC3 result in activation of macrophages. The activated macrophages produce neutrophil chemokines, like CXCL8. 5- *Mixed granulocytic asthma*, which can be caused from co-occurrence of all of the four aforementioned mechanisms. **Abbreviations:** IL = interleukin. TH = T helper. PGD₂ = prostaglandin D₂. TSLP = thymic stromal lymphopoietin. ILC2 = type 2 innate lymphoid cells. CXCL8 = C-X-C motif chemokine ligand 8. ILC3 = type 3 innate lymphoid cells. From Papi A, Brightling C, Pedersen SE and Reddel HK (2018) Asthma. *Lancet*, 391: 783–800.

Mechanism

These autoantibodies can cause various diseases via three major mechanisms; namely, induction of cellular destruction, induction of inflammation, and damaging physiological responses without tissue injury. In the following lines, each one of these is discussed in more depth.

Cellular destruction

Phagocytosis (by neutrophils or macrophages), antibody-dependent cell-mediated cytotoxicity (ADCC), and formation of membrane attack complex (MAC) are the primary mechanisms of cell death. Phagocytosis is caused by opsonization of the cells by antibodies and C3b, which binds to the antibody-antigen complex (Tak Mak and Jett, 2014). ADCC is another cytotoxic mechanism in the type II hypersensitivity. In ADCC, natural killer (NK) cells detect the antigen-antibody complexes by the Fc tail of the antibody and become activated. The activated NK cells release cytotoxic compounds such as perforins which lead cell death and apoptosis (Gómez Román et al., 2014). Lastly, the antibody-antigen complex activates the complement system, leading to formation of the MAC. The MAC disrupts the integrity of the cell membrane and causes cell lysis (Beenhouwer, 2018).

Inflammation

The inflammation caused by the antibody-antigen complex initiates with binding of C1 with the Fc tail of the antibody and complement activation. This attachment triggers a cascade during which chemotactic factors, such as C3a, C4a, and C5a, are produced. These mediators recruit immune cells, particularly neutrophils. When neutrophils are in the site, they release cytotoxic enzymes, such as peroxidase, proteinase B, and myeloperoxidase, leading to production of reactive oxygen species (ROS), which results in tissue damage (Abul et al., 2017a).

Cellular dysfunction

In contrast to the two previous mechanisms, this process is not cytotoxic. In this mechanism, attachment of the antibody to self-antigens, particularly receptors, leads to changes in the normal functions of the cell, which causes cellular dysfunction (Tak Mak and Jett, 2014).

Examples of diseases caused by type II hypersensitivity

Conditions mediated by cellular destruction

- Autoimmune hemolytic anemia (AIHA)

AIHA is an acquired hemolysis caused by production of antibodies against antigens of red blood cells (RBC) (Hill and Hill, 2018). AIHA is a rare disease with an estimated prevalence of 0.001 to 0.009% (Michel, 2010). Two different major types of autoantibodies are involved in AIHA: (1) warm and (2) cold anti-RBC antibodies (Quist and Koepsell, 2015). Warm autoantibodies (IgG), bind to the RBC at 37 °C and account for about 70% of AIHA cases (Kalfa, 2016). They typically induce phagocytosis of the RBCs (extravascular hemolysis) (Naik, 2015). However, they can also activate the complement system, which leads to intravascular hemolysis (Brodsky, 2019). Cold autoantibodies (IgM) bind to RBC at lower temperatures, resulting in complement activation and intravascular hemolysis (Berentsen et al., 2015). In almost 8% of patients, both cold and warm autoantibodies exist (Liebman and Weitz, 2017). Direct Coombs test is used for identification of the autoantibodies and diagnosis of AIHA (Shulman et al., 1985). However, in approximately 5% of cases the Coombs test can be negative. The most common paraclinical and clinical manifestations of AIHA include anemia, spherocytosis, fatigue, dizziness, pale skin, activity-induced breathlessness, and jaundice (Brodsky, 2019; Hill, 2015). The first line of AIHA treatment are glucocorticoids. Additionally, rituximab, cyclophosphamide, and azathioprine are also used in AIHA management (Liebman and Weitz, 2017). The last line of treatment is splenectomy, which is performed in resistant cases (Zanella and Barcellini, 2014).

- Immune thrombocytopenia (ITP)

ITP, with an estimated prevalence of 5.6 to 20 per 100,000 population (Moulis et al., 2014; Fogarty, 2009), is an autoimmune disease leading to destruction of platelets and causing a platelet count of $<100 \times 10^9/L$ (Lambert and Gernsheimer, 2017). ITP can affect children and adults. In children, the condition is typically self-limited, while in adults, it is usually chronic and more severe. Moreover, primary ITP is more common among children, but in adults, secondary ITP, which may result from viral infections, systemic lupus erythematosus, etc. is more common (Despotovic and Grimes, 2018). Anti-platelet antibodies which promote the destruction of platelets by the macrophages and circulating CD₈₊ T cells, are a key component in ITP pathogenesis (Zufferey et al., 2017). The spleen is the major site for the elimination of the platelets, with macrophages phagocytosing the opsonized platelets. Moreover, the immune system impairs the function of the bone marrow and reduces platelet production (Marini and Bakchoul, 2019). ITP can present with mild to severe bleeding (happening commonly in the skin or mucosal membranes), fatigue, and thrombocytopenia (Kohli and Chaturvedi, 2019). As ITP does not have an ideal diagnostic test, it is diagnosed by ruling out other differential diagnoses (Kelton et al., 2018). ITP treatment aims to provide an adequate platelet count to prevent severe hemorrhage. The first line of treatment are glucocorticoids and intravenous immunoglobulin. Splenectomy, immunosuppression, and

thrombopoietin receptor agonists are in the second line of treatment in ITP management (Cervinek, 2018; Neunert et al., 2019). Notably, in patients with severe bleeding, immediate platelet transfusion is required (Neunert and Cooper, 2018).

Conditions mediated by inflammation

- Goodpasture's syndrome or anti-glomerular basement membrane (GBM) disease

Goodpasture's syndrome is a rare rapidly progressive and potentially fatal autoimmune condition mediated by anti-GBM antibodies, which are targeted against the $\alpha 3$ chain of type IV collagen (McAdoo and Pusey, 2017). The $\alpha 3$ chain is inclusively expressed in the basement membrane of the kidneys and lungs. Thus, Goodpasture's syndrome can cause glomerulonephritis (by involving the kidneys) and alveolar hemorrhage (by involving the lungs) (Fig. 2) (DeVrieze BW, 2020). With an annual incidence rate of fewer than 10 cases per million, Goodpasture's syndrome accounts for 10–20% of rapidly progressive glomerulonephritis cases (Shiferaw et al., 2016). An interplay of genetic and environmental factors is involved in the etiology of this disease (Podzolkov et al., 2019; Henderson and Salama, 2018). In Goodpasture's syndrome, binding of autoantibodies with their ligands initiate inflammation through either activation of the complement system or the Fc receptor-dependent mechanism. In addition to the aberrant humoral immunity, at least in a subgroup of patients, glomerular autoreactive T-cells also play a vital role in the pathogenesis of Goodpasture's syndrome (Gulati and McAdoo, 2018). The clinical and paraclinical manifestations of this condition include acute kidney injury, hematuria, proteinuria, shortness of breath, hemoptysis, cough, pulmonary infiltrates on chest X-Ray, and iron deficiency anemia (Greco et al., 2015). Diagnosis is established by detecting anti-GBM antibodies in the serum or by kidney biopsy (Hellmark and Segelmark, 2014). Plasmapheresis, together with immunosuppression, is used in the treatment of Goodpasture's syndrome (Predecki and Pusey, 2019). In case of severe renal failure, renal transplantation may be required as well (Greco et al., 2015).

- Acute rheumatic fever (ARF)

ARF is an autoimmune response presenting two to three weeks after pharyngeal infection with *Streptococcus pyogenes* in 0.3–3% of cases (Siegel et al., 1961). Developing countries show the highest prevalence of ARF (Carapetis et al., 2016). Worldwide, the annual incidence of ARF is estimated at 5–51/100000 population, whereas in endemic regions, the annual incidence is more than 20/100000 population (Karthikeyan and Guilherme, 2018; Tibazarwa et al., 2008). The pathophysiology of ARF is speculated to be based on molecular mimicry and associated with polymorphisms of several genes involved in the innate and adaptive immunity (Azevedo et al., 2012; Baker et al., 2019). The streptococcal infection triggers production of antibodies and activation of T cells, both of which can target host tissues, including heart, joints, brain, and skin (Webb et al., 2015). The similarity of some antigens of *Streptococcus pyogenes* and several cardiac proteins is the main underlying cause of heart involvement, which can be life-threatening and is called rheumatic heart disease (RHD) (Marijon et al., 2012). RHD results from excessive inflammation, which can involve all three layers of the heart, but mostly affects endocardium. RHD is diagnosed by echocardiography (Liu et al., 2015). Cross-linking of antibodies in basal ganglia and joints can cause Sydenham's chorea and transient migratory polyarthrititis, respectively (Carapetis et al., 2016). Diagnosis of ARF is based on the modified Jones criteria (Table 2) (Pereira et al., 2017). Eradicating the infection with penicillin or erythromycin (in patients with penicillin allergy) is the primary treatment of ARF (Karthikeyan and Guilherme, 2018).

Fig. 2 Diffuse alveolar hemorrhage in addition to capillaritis in Goodpasture's syndrome. From Travis WD, Leslie KO, and Beasley MB (2018) Pulmonary vasculitis and pulmonary hemorrhage. In: Leslie KO and Wick MR (eds) *Practical Pulmonary Pathology: A Diagnostic Approach*, 3rd edn., Elsevier, ch. 11, 365–400.e5, ISBN: 9780323442848.

Table 2 Revised Jones criteria.

Major criteria	Minor criteria
Myocarditis	Fever
Joint involvement	Arthralgia
Erythema marginatum	Prolonged PR interval
Chorea	Elevated CRP/ESR
Subcutaneous nodules	

Diagnosis is established when there is laboratory confirmation of a recent group A streptococcal pharyngeal infection in addition to two major or one major and two minor criteria (Pereira et al., 2017).

Conditions mediated by cellular dysfunction

- Myasthenia gravis (MG)

MG is a chronic autoimmune disease causing weakness by affecting skeletal muscles and neuromuscular signal transmission (Gwathmey and Burns, 2015). Its prevalence is estimated to be 20 in 100,000 population (Phillips 2nd, 2003). Of note, in 10–15% of cases, MG is associated with an underlying thymoma (Romí et al., 2017). In MG, there is a disruption of stimulation of skeletal muscles. This stimulation is mediated by the attachment of presynaptic acetylcholine and acetylcholine receptors (AChR) in the membrane of these cells in the neuromuscular junctions (Hughes et al., 2004). In about 80% of cases, the disease is mediated by IgG1-3 autoantibodies against AChR (Gilhus et al., 2016). However, autoantibodies targeting either muscle-specific tyrosine kinase (MuSK) or low-density lipoprotein receptor-related protein 4 (LRP4) can also be responsible for the development of MG (Binks et al., 2016). AChR autoantibodies lead to its conformational changes, blockade of acetylcholine binding, and destruction of AChR by complement activation (Gilhus, 2016; Mantegazza et al., 2018). Apart from generalized disease of the muscles, MG may manifest as isolated eye involvement. In both conditions, ptosis, diplopia, and weak eye movements commonly occur due to involvement of extraocular muscles. In the generalized type, skeletal, bulbar, and respiratory muscles are also affected. As a consequence, the patient experiences fatigable chewing, dysarthria, dysphagia, expressionless face, dropped-head syndrome, and proximal weakness in limbs (Drachman, 2016). Diagnosis is established by detection of autoantibodies and electrophysiological studies. Acetylcholinesterase, immunosuppressive drugs, and corticosteroids are used in the treatment of this condition (Drachman, 2016; Mantegazza et al., 2018).

- Graves' disease (GD)

GD, the most common cause of hyperthyroidism, is an autoimmune disorder distinguished by over-stimulation and hypertrophy of the thyroid gland. With an estimated prevalence of 0.5%, GD commonly develops in the third-fifth decades of life. Notably, the lifetime risk of GD is six times higher in women compared to men (Brent, 2008). Genetic and epigenetic susceptibility are the key risk factors in GD (Cortes and Zeron, 2019; Bartalena, 2013). Environmental factors, like consumption of iodine and smoking, account for almost 20% of the risk (Bartalena, 2013). GD pathophysiology includes production of anti-thyrotropin receptor IgG1 subclass antibodies by B cells activated by autoreactive T cells. These antibodies act as an agonist and stimulate the production of thyroid hormones (Wemeau et al., 2018). Other autoantibodies can be found in GD as well. Some of these antibodies are involved in development of one of the characteristic features of GD; namely, ophthalmopathy (Fig. 3) (Smith and Hegedus, 2016). Manifestations of GD are similar to other disorders causing hyperthyroidism, including weight loss, fatigue, tremor, irritability, change of menstrual cycle, and erectile dysfunction. However, ophthalmopathy, dermatopathy, and acropachy (rare) are unique to GD (Antonelli et al., 2020). Presence of these symptoms, in addition to hyperthyroidism and diffused goiter (Fig. 4), suggests the GD diagnosis. In complicated cases, the diagnosis can be confirmed by radionuclide scanning or serological detecting of anti-thyrotropin receptor autoantibodies (Tozzoli et al., 2012). Treatments of GD include anti-thyroid drugs and ablative therapy, including ¹³¹I-radiotherapy and thyroidectomy (Bobanga and McHenry, 2019).

Type III (immune complex-mediated) hypersensitivity

Introduction

In this type of hypersensitivity, cross-linking of antigen-antibody pairs, which are produced during the normal immune response, leads to formation of unsolvable ICs. These complexes are usually positively charged; therefore, they have a high avidity to the basement membrane of kidney glomeruli and vessels, which have negative charges.

Mechanism

In case of excess production of immune complexes or impaired clearance of them, these complexes may get stuck in narrow channels of the body like capillaries and glomeruli. The deposition of these ICs activates the classical pathway of the complement which causes MAC mediated endothelial damage. After the endothelial injury, ICs infiltrate into the underlying tissue aggravating

Saunders, ISBN: 9780323189071, doi: <https://doi.org/10.1016/B978-0-323-18907-1.00082-2>.

complement activation, accumulation of the ICs, and leading to production of anaphylatoxins. Anaphylatoxins recruit mast cells, the secretion of which results in an increased vascular permeability. As a result of the increased vascular permeability and inflammation, leukocytes enter the tissue. In addition to the complement activation, neutrophils, macrophages, and NK cells can cause cellular damage by promoting phagocytosis or releasing lytic mediators. Although the deposition of the ICs can occur throughout the body, the most common sites of accumulation are small arteries, the synovia of joints, and glomeruli (Abul et al., 2017a; Delves et al., 2017a).

Examples of diseases caused by type III hypersensitivity

Serum sickness

Serum sickness is the first known type III hypersensitivity, recognition of which led scientists to identify pathogenicity of ICs for the first time in the early 1900s. Those days, serum of horses that had encountered diphtheria and had produced antibodies against it was used in the treatment of diphtheria in humans. Clemens von Pirquet, an Austrian scientist, noticed that approximately 1 week after the injection, patients develop arthritis, fever, and rash in response to the antiserum (Huber, 2006). This response was justified by production of antibodies directed to the antigens of the injected serum, which formed ICs by pairing with the antigens (Shulman, 2017). Nowadays, we know that serum sickness results from impaired clearance of ICs and their deposition in joints and parenchymal tissue (Lawley et al., 1984). These ICs can activate the classical complement pathway causing histamine release and inflammation (Rixe and Tavaréz, 2020). Medications such as rituximab, penicillin, cephalosporins (especially cefaclor), ciprofloxacin, and fluoxetine can cause this disorder (Cheong and Ooi, 2018; Maker et al., 2019). Notably, serum sickness is a self-limiting condition with a favorable prognosis (Joint Task Force on Practice et al., 2010). The symptoms can be managed by non-steroidal anti-inflammatory drugs (NSAIDs), antihistamines, and glucocorticoids (Clark et al., 2006).

Systemic lupus erythematosus (SLE)

SLE is a systemic chronic autoimmune disorder, the clinical manifestations of which are widely varied (Tsokos, 2011). With an estimated and increasing prevalence of 3–53/10000 people, SLE is most common among 15 to 45 year-old women (Stojan and Petri, 2018). While its pathophysiology is not fully understood, genetic susceptibility, like complement deficiencies, together with environmental factors, such as ultraviolet (UV) radiations, play a crucial role in its development (Lisnevskaja et al., 2014). The mechanism of SLE is mediated by defective clearance of apoptotic bodies, which is a result of impaired innate and adaptive immune responses. As a result, autoreactive antigen-presenting cells (APCs) capture the excessive nuclear antigens, which leads to activation of B and T cells. Activation of these cells gives rise to production of anti-nuclear antibodies, proliferation of CD8+ cytotoxic T cells, release of inflammatory cytokines, and tissue injury (Lisnevskaja et al., 2014; Fortuna and Brennan, 2013). Manifestations of SLE can be widely heterogeneous, including fatigue, fever, myalgia, arthritis, arthralgia, vasculitis, malar rash (Fig. 5), discoid, and photosensitivity. SLE can involve kidneys, gastrointestinal system, lungs, and eyes as well (Durcan et al., 2019). SLE patients are also more susceptible to coronary heart disease, and about 10% of them develop end-stage renal disease (Liu and Kaplan, 2018; Hanly et al., 2016). Diagnosis of SLE is based on the clinical manifestations, presence of anti-nuclear (ANA) or anti-double-stranded DNA (anti-dsDNA) or anti-Smith (Sm) antibodies, and evidence of SLE compatible nephritis in the kidney biopsy (Yu et al., 2014). Hydroxychloroquine, glucocorticoids, B-cell modulators, and immunosuppressive agents are some of the pharmacological treatments used in SLE management (Fanouriakis et al., 2019; Lisnevskaja et al., 2014; Tsokos, 2011).

Post-streptococcal glomerulonephritis (PSGN)

PSGN, the most common cause of childhood nephritis worldwide, occurs approximately 2 weeks after a group A streptococcus (GAS) skin or throat infection (Savige et al., 2019). Compared to the developed countries, where PSGN is more prevalent among

Fig. 5 Malar rash in a SLE patient, with a butterfly shape, crossing the nasal bridge, and sparing the nasolabial folds. From Nouh A, Speiser J, and Biller J (2015) Acquired neurocutaneous disorders. In: Islam MP and Steve Roach E (eds.) *Handbook of Clinical Neurology*, Elsevier, vol. 132, 29–73, <https://doi.org/10.1016/B978-0-444-62702-5.00003-2>.

elderly patients with debilitating conditions, in the developing countries, pediatric PSGN, with an annual incidence of about 9/100000, is more common (Rodríguez-Iturbe and Haas, 2016). Pathophysiology of PSGN is mediated by immune complexes. Antigens of GAS entering the circulation following the infection reside in glomeruli. Meanwhile, antibodies directed at these antigens are produced and form ICs with them either in the glomeruli or in the circulation, some of which aggregate in the glomeruli as well. Notably, before the activation of the adaptive immune response, streptococcal cell wall antigens activate innate immunity via the lectin pathway of the complement system. To date, two nephrogenic antigens; namely, nephritis-associated plasmin receptor (NAPlr) and streptococcal pyrogenic exotoxin B (SPE-B) have been found in GAS, which activate the alternative complement pathway, increase the production of circulatory ICs, and have high affinity to glomerular proteins (Eison et al., 2011; Rodríguez-Iturbe and Haas, 2016). Autoantibodies can also play a role in the PSGN pathophysiology (Balasubramanian and Marks, 2017). While PSGN is usually asymptomatic, some cases present with nephritic syndrome, exhibiting as hematuria, elevated creatinine levels, hypertension, and oliguria (Walker et al., 2014). The prognosis of PSGN is generally favorable. However, it can rarely lead to acute renal failure (VanDeVoorde, 2015). Detection of antistreptolysin O (in pharyngitis) and anti-DNase B (in impetigo) antibodies, together with low C3 levels, can help in the PSGN diagnosis (Maness et al., 2018). PSGN management is supportive treatment, unless an active infection is present, in which case antibiotics are used (Hunt and Somers, 2019).

Type IV (cell-mediated or delayed-type) hypersensitivity

Introduction

Type IV hypersensitivity is mediated by T cells and macrophages while other types are mediated by antibodies. Therefore, this reaction, which occurs at least 1–3 days after the initial exposure, is called delayed-type hypersensitivity (DTH) (Luo and Dorf, 2001). Type IV hypersensitivity is the underlying mechanism of many autoimmune disorders.

Mechanism

Activation of CD4+ T cells by tissue APCs can lead to tissue damage via two mechanisms: (1) cytokine-mediated inflammation and (2) direct cell killing by CD8+ cytotoxic T cells (CTLs). These mechanisms are described in the following lines.

Cytokine-mediated inflammation

Cytokines and other mediators produced by the immune cells play a key role in type IV hypersensitivity. For instance, T-helper 1 can promote activation of macrophages by interferon (IFN)- γ , recruit monocytes by tumor necrosis factor (TNF)- α and IFN- γ , aggravate proliferation of T-helper 1 cells by IL-2, and activate fibroblasts and angiogenesis by cytokines such as growth factors. Moreover, IL-17, which is released from T-helper 17, helps in the recruitment of neutrophils. The recruited neutrophils and macrophages produce toxic factors such as reactive oxygen species (ROS) and inflammatory mediators, which can lead to tissue injury (Tak Mak and Jett, 2014).

CTL mediated direct cell killing

Cross-linking of APCs with CD4+ T-helper cells trigger generation of CTLs. These T cells can be directed to foreign or autoantigens. Activation of CD8+ CTLs directed at self-tissue can lead to direct cell injury, an example of which is type 1 diabetes caused by CTL-mediated destruction of β cells of the pancreatic islets. Additionally, excessive reaction of CTLs directed at foreign antigens, whose main function is to defend against intercellular pathogens such as viruses, can lead to an excess damage in viral infections. The underlying cause of this extra damage is that CTLs are generally not able to differentiate between viral infections causing cell death and the less toxic ones. For instance, in some cases, like some types of hepatitis, the viral infection itself might not cause cell injury. Therefore, an excessive CTL response in these cases can be the primary cause of tissue damage (Welz et al., 2018).

Granulomas, which are accumulations of immune cells, are the hallmark of type IV hypersensitivity. Activated T-helper 1 cells produce pro-inflammatory cytokines, such as TNF- α and IFN- γ , leading to recruitment of monocytes to the tissue and massive activation of the macrophages. Some of these macrophages fuse and form giant cells, which are a key component of granuloma. In the granuloma, which is surrounded by fibroblasts, T-helper 1 cells can be detected as well. Generally, granulomas form in response to infections, such as tuberculosis, and play a protective role. However, they can also form in autoimmune disorders like Crohn's disease (Timmermans et al., 2016).

Examples of diseases caused by type IV hypersensitivity

Multiple sclerosis (MS)

MS is a demyelinating disease of the central nervous system (CNS) mediated by immune dysfunction. The prevalence of MS varies from 2 to 164 per 100,000 population in different regions (Collaborators, 2019; Howard et al., 2016). A complex interplay of mostly environmental factors, e.g., vitamin D deficiency, smoking, Epstein–Barr virus infection and to a lesser extent genetic susceptibility, e.g., HLA DRB1*15:01, is involved in the development of MS. MS pathology is characterized by multiple demyelinating plaques in the brain, particularly near bilateral ventricles, and the spinal cord. The exact pathogenesis and initial mechanisms of MS are widely unknown. Disruption in the integrity of the blood-brain barrier and aberrant adaptive immune responses seem to

play a pivotal role. Production of inflammatory mediators by T cells can damage oligodendrocytes; activate B cells, which produce antibodies against myelin molecules; and activate microglia and macrophages, which may phagocytose oligodendrocytes or aggravate the inflammation. Moreover, perforins secreted by CTLs may lead to axonal injury secondary to demyelination, which seems to be the leading cause of disability (Lemus et al., 2018). MS can present in four different forms, which are (1) relapsing-remitting multiple sclerosis (which is the most common form), (2) primary progressive MS, (3) secondary progressive MS, and (4) progressive-relapsing MS (which is the rarest form). Fig. 6 depicts the disease course in each form. The symptoms of MS are widely varied depending on the location of the plaques and the severity of the inflammation. Optic neuritis, fatigue, spasticity, bowel, bladder, sensory, and sexual dysfunction are among the most common manifestations of MS. Presence of at least two neurological attacks separated in time and space, detection of demyelinating lesions in magnetic resonance imaging (MRI), in addition to laboratory tests (such as blood and CSF analysis) are the clues to MS diagnosis. Treatment of MS is comprised of three sections: management of exacerbations, slowing the course of the disease with disease-modifying therapies, and symptomatic treatments (Michel et al., 2015; Dobson and Giovannoni, 2019).

Rheumatoid arthritis (RA)

RA is a chronic autoimmune condition characterized by inflammation, which primarily affects joints and can lead to disability. With an estimated prevalence of 0.5–1% worldwide, RA has a great burden for the patient and society (Silman and Pearson, 2002). Genetic susceptibility, epigenetic modifications, female gender, and smoking are the most prominent risk factors in RA (Deane et al., 2017). APCs Present foreign or autoantigens to naïve T cells, leading to their activation and differentiation. This results in activation of B-cell and macrophage (Aletaha and Smolen, 2018). The activated B cells may give rise to production of autoantibodies, like against citrullinated peptides antibody (ACPA), which activate macrophages, osteoclasts, and formation of ICs. These ICs aggregate in the synovium, trigger production of anti-IgG antibody (rheumatoid factor), and may cause complement activation. The activation of macrophages results in production of pro-inflammatory cytokines, which results in recruitment of immune cells and activation of fibroblasts (McInnes and Schett, 2011). The fibroblasts stimulate generation of osteoclasts via interaction of receptor activator of nuclear factor κ B ligand (RANKL) and RANK (Smolen et al., 2016). All of these processes lead to symmetric

Fig. 6 Four different disease courses in multiple sclerosis: The X axis shows time (age of the patients) and the Y axis shows disability.

Fig. 7 Rheumatoid nodules. From Erickson AR, Cannella AC, Mikuls TR (2017) Clinical features of rheumatoid arthritis. In: Firestein GS, Budd RC, Gabriel SE, McInnes IB, and O'Dell JR (eds.) *Kelley and Firestein's Textbook of Rheumatology*, 10th edn., 1167–1186, ch. 70, Elsevier, <https://doi.org/10.1016/B978-0-323-31696-5.00070-X>.

pain and swelling in small or large joints and morning stiffness. RA commonly involves joints of hand and feet. Additionally, 18–41% of patients present with extra-articular manifestations, the most common one of which is rheumatoid nodules (Fig. 7). Other extra-articular manifestations include interstitial lung disease, rheumatoid vasculitis, neurological involvements, and increased risk of cardiovascular disease (Marcucci et al., 2018). Early diagnosis of RA, which is mainly based on clinical examination, plays a vital role in RA management and prevention of disability (Allen et al., 2018). The number of involved joints, duration of symptoms, and presence of acute-phase reactants and autoantibodies are components of the 2010 RA classification criteria (Aletaha et al., 2010). RA management encompasses strategies targeting remission or reducing disease activity. Pharmacological agents used in the treatment include disease-modifying anti-rheumatic drugs (DMARD) and anti-inflammatory medications (Aletaha and Smolen, 2018; Littlejohn and Monrad, 2018).

Introduction

The alterations observed regarding the immune system during aging are summarized as immunosenescence (Singhal et al., 1978). Since the populations in the western countries are aging, due to an increased life expectancy and low birth rates, immunosenescence becomes more and more important for the western societies (Luy et al., 2020). Aging impacts all organ systems and mostly results in their decreased functionality. Regarding the immune system, most functions decrease as well. However, some activities are increased as part of immunosenescence, resulting in an overall complex alteration of the immune response and higher incidence of infections, tumors and autoimmunity (Fulop et al., 2019). The immune system is modified by dynamic changes throughout life. Two major factors drive these changes: sex and age. Both are obviously hard to influence in contrast to other factors impacting on the immune system like nutrition, physical activity, environmental pollution, etc. (Rink et al., 2015). The functionality of the immune system is therefore directly related to wellbeing and life expectancy. Investigations on elderly over 100 years, so-called centenarians, showed that these people have a better functioning immune system than the average of normal aged people, which includes a high number of frail elderly (Borras et al., 2020).

Whereas all healthy humans are born with a powerful innate immunity, the adaptive immunity improves during childhood through the contact to harmless and harmful foreign organisms and particles. The immune system undergoes major changes during puberty, resulting in an initially stronger immune response in women than in men. During menopause, the efficiency of the immune response in women starts to decline. After the age of 65 years the immunity of men and women is nearly equal and starts to deteriorate, which results in increased numbers of infections and cancers. However, the number of autoimmune diseases increases with age as well. Interestingly, the immune response of centenarians shows a less pronounced decline and is comparable to adults under the age of 60 years.

In a long-term observational study, starting in 1989 with elderly over 80 years, which were monitored until the age of 90 years (i.e., nonagenarians), an immune risk phenotype (IRP) has been defined by Swedish scientists. Changes leading to the IRP are not observed in young people, so that life expectancy could not be estimated. However, in elderly the IRP shows characteristic changes of the immune system with a decreased functionality which resulted in death within the next years (Wikby et al., 2008). In the normal population the decreased function of the immune system becomes obvious long before, since the rate of infections and tumors increases strongly with age (Katzir et al., 2021). The infection-dependent death rate increases steadily from the age of 50 years and is ten times higher at the age of 80 years compared to the rate at an age below 50 years. Interestingly, the increase in the death rate is delayed in women, which is related to the onset of menopause. After reaching the age of 75 years the infection-related death rate in men and women is equal (Rink and Dalhoff, 2004).

Since we cannot stop aging, the only way to improve the immune response is to decrease the biological aging by a positive impact via a healthy lifestyle, including balanced nutrition and exercise. It is important to mention that the aim of immunosenescence research or immune gerontology is not immortality, since human life is restricted to around 120 years (the oldest person on earth became 122 years) (Niedermüller and Hofecker, 2004). The aim of this field of research is to improve the immune capacity, consequently increasing the number of healthy years so that an individual's optimal life expectancy will be reached. Therefore, the most important question is how to reach the immune capacity of centenarians and to live a healthy life until the personal genetics

determine life's end. Most centenarians die between the age of 104–106 years, but without a long period of illness or frailty (Borras et al., 2020). To explain this miracle, the age-related differences between the immune system of normal elderly and centenarians must be understood to uncover and address the immunological issues responsible for frailty (Nielsen et al., 2021). Based on a number of studies with SENIEUR-elderly, a group specified by a complex protocol, those differences were clearly defined (Ligthart et al., 1984, 1990a). This definition is important since in contrast to the field of pediatrics, still no age-specific standard values for laboratory parameters in geriatrics are defined, although it is well known that a number of parameters show age-related alterations without any related diseases (Harm, 1997). However, these various alterations of standard clinical laboratory parameters seems to appear randomly up- or down-regulated. Often one parameter is always altered in the same direction, but biochemically related parameters are changed into a different direction. Therefore, it helps to categorize these observations for “normal elderly,” SENIEUR-elderly and centenarians. “Normal elderly” describes the average population over 65 years including frail elderly and elderly with diseases, since a couple of diseases have an age-independent effect on the immune system. In comparison to the SENIEUR-elderly, the normal elderly are often non-healthy, but the regular medical case, since the SENIEUR protocol excludes 90% of the elderly population. Therefore, normal elderly could be split into healthy (but not selected with SENIEUR criteria) and frail elderly. Table 1 shows some major differences of the immune system of these four major groups of elderly. In the following paragraphs, the age-related alterations of the different parts of the immune system will be discussed in detail in the light of healthy elderly (Compte et al., 2019). Fig. 1 shows a summary of all functions disturbed in the aged immune system.

Innate immune system

The innate immune system includes physical barriers of the body like skin and mucosa as firewalls. These barriers are less effective in elderly, since their skin is thinner and drier (Wlaschek et al., 2021). On dry skin, less fat soluble, antimicrobial defensins are present. Mucosal surfaces show a loss of moisture as well, which facilitates the settlement of bacteria. Elderly have a decrease in cilia function, which leads to a reduced export of bacteria from the body and facilitates bacterial settlement (Bailey et al., 2018). In addition, the cough reflex to eject bacteria is decreased (Lalley, 2013). Those disturbances specifically explain the age-related increase in pneumonia susceptibility. Gastrointestinal and bladder infections increase with age as well. This is related to a reduced acidity of the gastric acid since the low pH normally kills bacteria. In the bladder, the bacteria stick to the surface more easily, due to a decreased diuresis since normally the urine flow flushes out the bacteria. The reduced diuresis is boosted by less drinking as a consequence of the absence of thirst. The weakness of the physical barriers in the elderly reduces the threshold for bacterial numbers, sufficient to establish an infection (Jump and Canaday, 2017).

Table adapted and updated from Compté N, Pepersack T and Goriely S (2019) Frailty in old age is associated with altered cytokine production in response to TLR ligation. In T Fulop, C Franceschi, K Hirokawa and G Pawelec (eds.), *Handbook of Immunosenescence*. 2nd edn, pp. 2417–2434, Springer International Publishing: Cham. doi:10.1007/978-3-319-99375-1_152.

Fig. 1 Summary of immunosenescence. All stages of the immune response are altered in aging, starting with the disruption of the maturation of leukocytes in the bone marrow (BM) (upper left). Hematopoietic stem cells (HSC) differentiate more towards common myeloid precursors (CMP) than to common lymphoid precursors (CLP), leading to a reduced production of lymphocytes in contrast to a normal production of myeloid cells (mainly monocytes (M) and polymorph nuclear neutrophils (PMN)). However, the up-regulation of PMN release from the bone marrow is disturbed in the elderly, due to a reduced signal transduction of the cytokines (e.g., interleukin (IL)-1, granulocyte colony stimulating factor (G-CSF), granulocyte/macrophage CSF (GM-CSF)) responsible for their differentiation. Since the thymus

(upper right) is shrinking with age (thymic involution), the production of new T cells without antigen contact (naïve T cells) is reduced. Furthermore, in both T and B cells, the number of long living clones increases. The interaction between different leukocytes as part of the immune response in the spleen and lymph nodes (lower right) is disturbed as well. Both T cell-dependent and T cell-independent B cell activation are reduced in aging, mainly due to a decreased signal transduction of the B cell receptor (BCR) and a reduced BCR expression in naïve B cells (membrane-associated IgM). However, the antigen-independent B cell activation, e.g., by cytokines like IL-4, is increased, leading to a proliferation of memory B cells (mB) and an increased production of IgG and IgA by mB and plasma cells (PC). The interaction between T cells and dendritic cells (DC) or macrophages (Mφ) is disturbed as well. The activation through the T cell receptor (TCR) is reduced and major cytokines for inducing a T helper (TH) 1 response (e.g., interferon (IFN)- α and IL-12) are less produced. This leads to a reduced production of TH1 cytokines (e.g., IL-2, IFN- γ) as well. On the other hand, as part of inflammaging, Mφ produce increased amounts of the pro-inflammatory cytokines IL-1 and IL-6, as well as IL-10, which stimulates TH2 cells and the production of IL-4. This results in a dysbalance of TH1 and TH2 cells. In the skin and peripheral tissues (lower left) this leads to a chronic inflammatory process even in the absence of a pathogen, i.e., without a danger signal. On the other hand, this chronic inflammation results in a reduced activation-induced immune response. Furthermore, the sentinel cells of the immune system (i.e., DC and Mφ) as well as the PMN show reduced reactivity and killing activity, but a spontaneous release of pro-inflammatory cytokines. Although the ratio between TH17 cells and regulatory T cells (Treg) increases in the blood, upon stimulation this turns around preventing an activation of the adaptive immune system. Finally, the activated endothelial cells produced fewer recruiting factors for leukocytes (e.g., G-CSF, GM-CSF) and thereby closing the vicious cycle of the disturbed immune response in aging. This figure is adapted and updated from Rink L, Kruse A and Haase H (2015) *Immunologie für Einsteiger*. 2nd edn, Springer Spektrum: Berlin. doi: 10.1007/978-3-662-44843-4.

The functions of the complement system itself are almost unaffected by aging, as long as the liver metabolism is intact. Some hepatic factors like acute phase proteins are even elevated in serum. However, it is a matter of debate if this increase is due to a chronic inflammatory process in the elderly, called inflammaging, or due to the frequent dehydration and thus concentrating serum factors. However, the alterations on the cellular level are more prominent.

Granulocytes and mast cells

The overall number of granulocytes in the blood remains largely stable during aging but the numbers for the three subtypes change differently. In contrast, the function of all granulocyte subtypes is altered markedly in the elderly (Uciechowski and Rink, 2019). Changes in granulocytes and mast cells are summarized in Table 2.

Basophils

The total number and percentage of basophils in the blood is significantly decreased in aging. Functions of basophils are altered as well. Basophils show a delayed activation, but an increased release of histamine in the elderly. However, the knowledge on basophils in aging is still limited (Uciechowski and Rink, 2019).

Eosinophils

Research data on eosinophils in aging is scarce as well. The number of eosinophils is decreased in elderly. Eosinophils seem to have a lower chemotactic activity in aging, but data are controversial (Uciechowski and Rink, 2019). The production of reactive oxygen species (ROS) is decreased and stimulation-induced degranulation is delayed in the elderly (Mathur et al., 2008).

As a result from dysfunctions in eosinophils and basophils, the defense against parasites and fungi is markedly decreased in elderly.

Neutrophils

The changes of neutrophils (or polymorphonuclear neutrophils (PMN)) during aging are well studied. The number of PMN in the elderly is normal or slightly increased. Although the basal number of PMN in the blood might be increased, the production rate in the bone marrow is unchanged. The infection-induced increase in granulopoiesis is markedly decreased (Uciechowski and Rink, 2019), mostly due to a disturbed signal transduction of G-CSF (granulocyte colony-stimulating-factor), whereas GM-CSF-induced signaling (granulocyte/macrophage CSF) is unaffected (Chatta et al., 1993; Fulop et al., 2019). Normally, G-CSF and GM-CSF inhibit apoptosis in PMN during an infection, but not in aging (Fulop Jr et al., 1997; Tortorella et al., 1998). In addition to the higher production, the inhibition of apoptosis is a second reason why the number of PMN in young people quickly increases as an early response of the immune system. Together these two age-related changes lead to a relative deficiency or even an exhaustion of PMN during infection in the elderly. This is also the reason why a decreased lifespan of PMN is observed in the elderly. The main functions of PMN, i.e., chemotaxis, phagocytosis, oxidative burst (ROS production) and intracellular killing, are all decreased in aging (Uciechowski and Rink, 2019). The reduced chemotaxis is once more based on the disturbed signal transduction of chemotactic factors. In contrast to the chemotaxis, the rolling and attachment of PMN to the endothelium before diapedesis is even elevated due to an increased expression of adhesion molecules (e.g., CD15). However, this increased contact between PMN and the endothelium is a disadvantage, since it causes damage of the endothelium. PMN exert enhancing effects in the late phase of the immune response, which is disturbed in the elderly due to a reduced expression of the Fc γ -Receptor-III (CD16) on the surface of the PMN (Uciechowski and Rink, 2019). However, although the total number of PMN does not change, hematopoietic stem cells (HSC) of elderly preferentially differentiate into myeloid cells (Garrrick et al., 2019).

In conclusion, the defense against bacteria and fungi is markedly decreased in elderly due to the reduced recruitment and killing capacity of neutrophils.

Mast cells

The number of mast cells in skin and other tissues increases significantly with age and is related to tissue fibrosis. Mast cells show an unspecific activation in aging but their function and activation upon stimulation are decreased (Kutukova et al., 2016). Moreover, their main function as early sensors of pathogens is disturbed. Altogether, the knowledge on mast cells in aging is very limited in contrast to that on granulocytes. In conclusion, the elevated numbers of mast cells in aging have rather a negative effect.

NK cells

The number of natural killer (NK) cells and more prominently NKT cells increases with age. The increase in NK cells is mostly based on long-lived NK cells, whereas the NK cell production in the bone marrow decreases (Campos et al., 2019). However, the functionality of NK cells decreases even in SENIEUR elderly. The reduced activity becomes apparent in a decreased killing rate, proliferation, activation, interferon (IFN)-γ and chemokine production of the NK cells (Borrego et al., 1999a,b). The decreased expression of CD25 (high affinity interleukin (IL)-2 receptor) (Bartoloni et al., 1990) and CD69 (general activation marker of lymphocytes) (Borrego et al., 1999a,b) indicates a reduced activation rate. Since the perforin concentration in the NK cells of elderly remains stable, the decreased activation seems to be the primary explanation for the disturbed killing (Mariani et al., 1994). The lower production of the mentioned cytokines leads to a reduced activation of other leukocytes in the early phase of the immune response. Interestingly, the NK and NKT cell activity in centenarians is normal or even slightly elevated (Levy et al., 1991; Steinmann and Hartwig, 1995). Age-dependent alterations in NK cells are summarized in Table 3.

Table updated from Rink L, Kruse A and Haase H (2015) *Immunologie für Einsteiger*. 2nd edn, Springer Spektrum: Berlin. doi: 10.1007/978-3-662-44843-4.

In conclusion, the defense against viruses and cancer is markedly decreased in the elderly due to the reduced killing capacity of NK cells and the diminished recruitment and activation of other cells by the NK cells in the early phase of the immune response.

Monocytes, macrophages, and dendritic cells (DC)

Antigen presentation is a prerequisite for activation of the adaptive immune system. The main antigen presenting cells in the early immune response are monocytes/macrophages and dendritic cells (DC), including their tissue resident subtypes. The number of monocytes and DC in the blood of the elderly is equal to that of young adults (Fulop et al., 2019). In contrast, numbers of skin DC (Langerhans cells) decrease with age (Chambers and Vukmanovic-Stejic, 2020). Data on other tissue resident macrophages and DC are rare and not consistent but decreased numbers can be expected as well. In contrast to most other cell types, the monocytes/macrophages of elderly show an augmented inflammatory response, e.g., an overproduction of IL-1, IL-6 and other cytokines (see section “Immune regulation by cytokines”). In contrast to granulocytes, the phagocytic activity of monocytes/macrophages is close to normal. However, the antigen presentation and their capability to activate T cells are reduced in monocytes/macrophages and DC (Rich et al., 1993; Agrawal et al., 2007). Pinocytosis and endocytosis decline with age in DC as well. Collectively, the activity of antigen presenting cells is disturbed. However, recent data indicate that the number of MDSC (myeloid-derived suppressor cells) is increased in aging (Verschoor et al., 2013; Alves et al., 2018), which augments the deregulated balance within the myeloid system. Age-related changes in monocytes/macrophages and DC are summarized in Table 4 (Della Bella, 2019).

In conclusion, the defense against all types of pathogens is markedly disturbed in elderly due to the impaired antigen presentation by monocytes/macrophages and DC and the imbalance triggered by an overproduction of pro-inflammatory cytokines and the increased number of MDSC.

Adaptive immune system

The adaptive immunity, especially the T cell system, is stronger impaired by aging than the innate immune system. The differentiation of hematopoietic stem cells to the lymphoid lineage is impaired, whereas the differentiation to the myeloid lineage is favored due to epigenetic changes (Garrick et al., 2019). In general, the number of naïve lymphocytes decreases, and the number of memory cells increases. Thus, the response to novel antigens becomes weak, whereas elderly are protected from most common infections as long as the memory system is stable. However, elderly are prone to infections by pathogens with a high mutation rate, like the influenza virus, where the constant change in antigens becomes a new challenge for the aging immune system.

T cells

The impaired function of the T cell system was one of the first observations of immunosenescence. The function of no other cell type is as strongly disturbed during aging as found for T cells. The resulting problems are often compared to HIV (human immunodeficiency virus) infections as a model of advanced aging of the immune system (Quiros-Roldan et al., 2020). One common problem of aging and HIV infection is the chronic stimulation of T cells by latent herpes viruses, which continuously stimulate the reactive T cells clones and thereby decreases the remaining T cell repertoire, due to enhanced numbers of the herpes virus reactive T cell clones (Nikolich-Zugich, 2008). The most prominent change during aging is the involution of the thymus (Henry, 1967). Since all T cell populations mature in the thymus, the loss of thymic function results in a decrease in the number of T cells (Sansoni et al., 1993). However, in contrast to the original discovery, it is now clear that the thymus is only partially replaced by fat tissue and that

centenarians have a nearly functional thymus. Therefore, the thymic output, i.e., the number of newly produced naïve T cells (indicated by a TREC (T cell receptor rearrangement excision cycle)), is a marker of thymic activity and the immunological age (Pinti et al., 2010). However, normally the thymus starts to degenerate from the third decade of life and is replaced by fat tissue (Elyahu and Monsonego, 2021). The thymic involution is mainly induced by the male and female sex hormones, i.e., testosterone and estrogen, and by ROS (Bodey et al., 1997). Some cytokines like IL-7 can slow down or even reverse the thymic involution, which is currently evaluated in clinical studies in a clinical experimental phase. The endogenous IL-7 production declines with age (Pangrazzi et al., 2017; Bradburn et al., 2018). The decreasing thymic output is directly correlated to the low number of T cells in the blood. However, the functional disturbances are much more significant, since nonfunctional CD28⁻ T cell clones accumulate with age, suggesting only a slight decrease in T cells (Grabstein et al., 1993; Posnett et al., 1994). Furthermore, some original papers did not observe decreased T cell numbers, probably due to using CD2 as T cell marker instead of CD3. The latter is currently state of the art and CD2 is expressed by NK cells, which are increased with age (Xu et al., 1993).

Numbers of CD8⁺ cytotoxic T cells (CTL) decrease stronger in the elderly than the numbers of CD4⁺ T helper cells, which results in an increased CD4/CD8 ratio (Sansoni et al., 1993). Since CTL are mostly needed to defend viral infections, viral infections increase with age. As pointed out before, the numbers of memory T cells (CD45R0⁺) increase with age, whereas the numbers of naïve T cells (CD45RA⁺) decrease (Xu et al., 1993). This explains the weak response to new (neo) antigens, whereas the response to well-known antigens (recall antigens) remains quite normal.

In addition to the decline in T cell numbers, their function is disturbed. T cells of elderly show an impaired response to stimulation since they are already chronically pre-activated. This pre-activation becomes apparent by the higher numbers of CD25⁺ (high affinity IL-2 receptor) and HLA-DR⁺ T cells (Sansoni et al., 1993). However, the pre-activation is the main reason for the overall reduced T cell response upon activation and the high clonal exhaustion, observed in the elderly. The poor activation of the T cells of elderly results in less proliferation of the T cells. Proliferation is a prerequisite for the adaptive immune response (Pawelec et al., 1999), since this depends on the clonal selection of the antigen-specific lymphocytes. Without proliferation of the T cells, the number of effector T cells will be too low for pathogen clearance. Furthermore, the activated T cells may be clonally exhausted, and a new memory cannot be established. The clonal exhaustion due to AICD (activation-induced cell death) is increased by the overall higher apoptosis rate of leukocytes in the elderly (McLeod, 2001). The reduced activation is based on an impaired T cell receptor (TCR) signal transduction and on a lack of survival signals. The ζ -chain of the CD3 signal transduction complex of the TCR shows a reduced phosphorylation and the transcription factor c-fos is lowly expressed in the elderly (Song et al., 1992; McLeod, 2001). Additionally, the balance between pro-apoptotic (e.g. Bax) and anti-apoptotic proteins (e.g., Bcl-2 and p53) in T cells is shifted towards the pro-apoptotic ones. Furthermore, the number of T cells expressing the death receptor CD95 and its ligand is increased. Elevated apoptosis is more prominent in the naïve T cells of elderly, which further contributes to the lower quotient of naïve to memory T cells (CD45RA⁺/CD45R0⁺).

As mentioned above, the number of CD28⁻ T cell clones increases with age. These cells are anergic, which means that they cannot respond to their specific antigen. Naïve and resting T cells need at least two signals for their activation: First an antigen-specific signal through the TCR and second via the costimulatory molecule CD28. Consequently, these CD28⁻ long-living T cell clones cannot be activated. So far it is unclear, why these unresponsive CD28⁻ T cell clones have a much longer half-life than other T cells. In addition, these T cell clones lack CD40L (CD154), which is the ligand for CD40 expressed by B cells and other antigen presenting cells and necessary for T cell help (Weyand et al., 1998). Most of the CD28⁻ T cell clones are CD8⁺ and represent the T cell counterpart to the long-living B cell clones in MGUS (monoclonal gammopathy of undetermined significance). The survival of the anergic T cell clones is maintained by signal transduction through the IL-2-receptor and CD2, which is not impaired in contrast to TCR-induced signaling via CD3 (Song et al., 1992). However, the anergic T cell clones displace normal T cells in blood and lymphatic tissues, resulting in a higher functional loss than estimated due to reduced T cell counts.

The number of regulatory T cells (Treg) in the blood is decreased in elderly, while the number of TH17 cells is increased, leading to an increased TH17/Treg ratio. However, during stimulation this ratio turns around in the elderly, resulting in a reduced TH17/Treg ratio, which explains the disturbed antimicrobial response (Schmitt et al., 2013). Furthermore, the number of memory Treg cells is increased in the elderly (van der Geest et al., 2014). The age-related changes in the T cell system are summarized in Table 5. In conclusion, the capacity of CTL to kill virus infected cells is reduced in the elderly and the function of T helper cells is disturbed, leading to a dysbalanced immune response against other pathogens as well. Finally, the impaired proliferative capacity of T cells limit the strength and duration of the immune response

B cells and antibodies

The humoral immunity is disturbed in aging as well. Clinically, this is revealed by a disturbed vaccination response (Grubeck-Loebenstein et al., 2009). The number of B cells decreases with age (Sansoni et al., 1993). The production of B cells in the bone marrow is reduced, due to a differentiation stop at an early stage (Quaglino et al., 1996; Zheng et al., 1997). However, the number of B cells in the spleen remains stable, since these B cells have a prolonged lifespan (Klinman and Kline, 1997). Therefore, it is still surprising that the T cell-independent B cell activation is reduced in the elderly, since this is normally due to a reduced number of marginal zone B cells in the spleen. A possible explanation is the reduced expression of IgM on the B cell surface in aging (Klinman and Kline, 1997).

Comparable to the increased number of memory T cells, numbers of CD27⁺ memory B cells increase as well, leading to a reduced antibody repertoire with increasing age. This problem is augmented by single highly proliferating B cell clones. Mostly, these B cell

Table updated from Rink L and Dalhoff K (2004) Altersspezifische Veränderungen des Immunsystems und deren assoziierte Krankheitsbilder. In D Ganten, K Ruckpaul and A Ruiz-Torres (eds.), *Molekularmedizinische Grundlagen von altersspezifischen Erkrankungen*, 1st edn, pp. 429–464, Springer: Berlin. doi:10.1007/978-3-642-18741-4_16.

clones are MGUS and only a minority are malignant B cell neoplasia. 38% of elderly have a monoclonal gammopathy, whereas this is observed in only 1–3% of middle-aged adults. Even SENIEUR elderly have a MGUS rate of 11% (Ligthart et al., 1990b)

Functional B cells show a reduced expression of IgM on the cell surface and a disturbed signal transduction of the B cell receptor (BCR) (Whisler et al., 1991a,b), leading to a reduced T cell-dependent and—independent B cell activation. In combination with the reduced T cell response and since most B cell responses are T cell-dependent, the resulting impairment is even worse since the functional disturbance in either the T cell or the B cell is sufficient to disrupt their interaction. This results in a reduced antibody production in response to pathogens as well as to vaccination. Furthermore, the quality of the antibodies produced is lower in aged people, since the affinity maturation by hypermutation is disturbed as well (Miller and Kelsoe, 1995; Zheng et al., 1997). However, the antigen-independent B cell activation by IL-4 and other mediators is normal (Fernandez-Gutierrez et al., 1999). Since the induction of memory B cells is disturbed in the elderly, booster vaccinations are required in shorter intervals to provide protection. Alternatively, the use of higher antigen doses or adjuvants are recommended for vaccination of the elderly.

Although the B cell system is impaired, the immunoglobulin concentration in the serum of elderly is increased (Cakman, 1996). This increase is based on significantly higher amounts of IgG1, 2, 3 and IgA, whereas the levels of the other immunoglobulins are stable (de Greef et al., 1992). Interestingly, specific IgE levels, responsible for type-I allergies, are reduced in the elderly (Nakazawa et al., 1994). However, the number of autoantibodies and thereby the incidence of autoimmune diseases increases with age. Despite the detection of autoantibodies in asymptomatic elderly, the onset of autoimmune diseases after the age of 65 years is rare (Bryl and Witkowski, 2019). While both organ-specific and non-organ-specific autoantibody levels increase with age, in SENIEUR elderly and centenarians mostly the non-organ-specific autoantibodies are observed. Table 6 summarizes the changes in the B cell system.

In conclusion, the decreased capacity to produce antigen-specific antibodies upon stimulation leads to a higher frequency of infections. The low vaccination response and shortened memory function further add to the decreased protection.

Immune regulation by cytokines

The regulation of the immune response is largely governed by cytokines and adhesion molecules. Since differences in the expression of adhesion molecules were discussed already for the respective cell types, the following paragraphs will focus only on disturbances in the cytokine system. In contrast to the alterations in the leukocyte populations, with increasing or decreasing numbers, the changes in the cytokine system are quite heterogeneous. Production of most pro-inflammatory cytokines is elevated upon stimulation and cytokines are frequently even produced constitutively without a danger signal. This phenomenon is called inflammaging (Franceschi et al., 2000), describing the chronic inflammation found regularly in the elderly. Some cytokines like IL-6 are even used as aging markers, since increased IL-6 levels correlate with the grade of frailty and with lower response to vaccination. Interestingly, disturbances are cytokine but not cell type specific. For example, monocytes/macrophages and DC produce more pro-inflammatory IL-1, IL-6 and tumor necrosis factor (TNF)-α, whereas the same cells have a defect in the production of the antiviral IFN-α (Cakman et al., 1997). The increased production of the pro-inflammatory cytokines leads to a chronic inflammation accompanied by an acute phase response, resulting in increased serum levels of C-reactive protein (CRP) and α2-macroglobulin. Furthermore, this pro-inflammatory cytokine cocktail activates lymphocytes antigen-independent, which is one reason for the observed unspecific T cell activation and increased antibody production. Unfortunately, this chronic activation has rather negative side effects and does not enhance the memory function, since pre-activated cells cannot efficiently be further activated, which is a prerequisite for an effective immune response.

Beside this pro-inflammatory response, the balance between immune cells is affected by aging. The ratios of TH1/TH2 and TH17/Treg are disturbed. Lymphocytes of elderly produce less of the TH1 cytokine IFN-γ, whereas the production of the TH2 cytokine IL-4 is unchanged, resulting in a reduced TH1/TH2 ratio. The production of the TH17 cytokine IL-17 is diminished as well. Together this leads to a reduced activation of effector T cells (Cakman et al., 1996, 1997; Schmitt et al., 2013). In conclusion, the alterations in the cytokine system, which are summarized in Table 7, lead to a weak immune response against viruses and bacteria.

Table updated from Rink L and Dalhoff K (2004) Altersspezifische Veränderungen des Immunsystems und deren assoziierte Krankheitsbilder. In D Ganten, K Ruckpaul and A Ruiz-Torres (eds.), *Molekularmedizinische Grundlagen von altersspezifischen Erkrankungen*, 1st edn, pp. 429–464, Springer: Berlin. doi:10.1007/978-3-642-18741-4_16.

Infectious diseases in the elderly

Infectious diseases increase dramatically with age, with the exception of the sexual transmitted diseases. The risk for pneumonia in those older than 65 years is 3–5 times higher. 50% of people dying from pneumonia are over 65 years. The mortality from pneumonia increases from 5–8% to 80% in elderly over 85 years. In the US, pneumonia is the most common cause of infection-associated deaths in the elderly and the fourth most frequent overall cause of death (Castle, 2000; Rink et al., 2015). 90% of the estimated excess deaths by influenza occur in the elderly over 65 years. Therefore, vaccinations against pneumococci, influenza and now corona virus are of high importance, especially for the elderly. However, even if the seasonal influenza vaccine matches well and protects 70–90% of the adults under 65 years, only 30–40% of the elderly are protected. For pneumococcal vaccination, the protection is also age-dependent. Five years after vaccination, 70% of elderly under 75 years are protected, whereas it declines to 53% in the 75–85 year-olds and finally reaches only a protection rate of 22% in the very old (>85 years) (Castle, 2000). During the COVID-19 (corona virus disease 2019) pandemic in Germany, 97% and 89% of the 73.445 deaths between March 2020 and March 2021 were 60 years and older and 70 years and older, respectively. Therefore, old age is the highest risk factor for a critical illness from the corona virus (Robert Koch-Institute, 2021).

Herpes zoster, i.e., the reactivation of chicken pox, is a typical age-related disease. The lifetime incidence is 10–20% counting all infected people, which increases to 50% for those older than 80 years. This increased reactivation is directly related to the decline of the T cell response, since all latent herpes viruses are under control of T cells (Rink et al., 2015). In addition to chicken pox, reactivation is often observed for cytomegalovirus (CMV) and tuberculosis. However, since the tuberculosis rate dramatically decreased in Western countries after the Second World War, this is mostly a problem in the generation born before the 1940s. In contrast, CMV is still the most frequently transferred virus during pregnancy and therefore the infection rate in the population is very high. Studies on the IRP imply, that the chronic stimulation of the immune system by CMV accelerates the decline of the T cell system. This seems comparable to HIV infection, where forced aging of the immune system is observed as well (Quiros-Roldan et al., 2020).

Table updated from Rink L and Dalhoff K (2004) Altersspezifische Veränderungen des Immunsystems und deren assoziierte Krankheitsbilder. In D Ganten, K Ruckpaul and A Ruiz-Torres (eds.), *Molekularmedizinische Grundlagen von altersspezifischen Erkrankungen*, 1st edn, pp. 429–464, Springer: Berlin. doi:10.1007/978-3-642-18741-4_16.

Urinary tract infections (UTI) increase with age as well. For example, the asymptomatic bacteriuria is enhanced, from a prevalence of 1–5% in healthy premenopausal women to 4–19% in healthy elderly and finally 15–50% in institutionalized elderly. Symptomatic UTI in women aged 65–74 years showed an increased incidence of 9–11 cases per 100 person-years, which further increases to 11.4–14.3 cases in women aged 75–84 years and ended up in 14.7–19.8 cases per 100 person years in those over 85 years. UTI in men increased as well by age, but on a lower level (Rodriguez-Manas, 2020).

Although the efficient treatment of bacterial, viral, and other infectious diseases with antibiotics, virostatics, antimycotics and other drugs has much improved, an intact immune system is needed to prevent infections and to slow down the spreading of the pathogens before starting the treatment. Also, opportunistic pathogens may take their chance in elderly. Thus, improvement or stabilization of the immune functions during aging is important to prevent death from infectious diseases.

Conclusion

The increasing knowledge on the differences between frail and healthy elderly, as well as on the distinctive immune characteristics of SENIEUR-elderly and centenarians gives us the chance to understand why people may reach their potential maximal age or not. Standard health check-ups should be improved by compiling immunological parameters to generate an individual immune risk profile. In the future, we may be able to push the immune system towards a healthy decline like in centenarians, which will increase the healthy life span, but not the overall life expectancy. If we are successful, this will decrease the burden of infections and cancers in the very old.

Introduction

Cancer is one of the prevalent diseases affecting a lot of people around the world. It has been predicted that new cases of cancer will be increasing to 22.2 million in 2030 while it was 18.1 million in 2018 (Bray et al., 2018). It is the second cause of death worldwide and accounted for 9.6 million deaths in 2018 (Bray et al., 2018). Researchers and physicians have tried their best to cure cancer; however, limited improvement in overall survival has been achieved and the mortality rate is still high (Pishvaian et al., 2020). Therefore, a deep understanding of cancer pathophysiology is necessary to discover bench-to-bedside diagnostic, predictive, and prognostic biomarkers and develop novel preventive and therapeutic modalities. Immune evasion is one of the hallmarks of cancer highlighting the remarkable role of the immune system in eradication of cancer. It has also been revealed that the immune system can promote cancer development (Vinay et al., 2015). Hence, improving the understanding of cancer immunology can assist researchers to develop improved modalities and potent biomarkers.

Immunotherapy is the fourth pillar of cancer treatment recently applied to improve the survival of patients with cancer (Hunter, 2017). The first evidence of successful cancer immunotherapy was reported in 1891 by Coley. He examined a bacterial toxin consisted of killed *Streptococcus pyogenes* and *Serratia marcescens* for treatment of a young patient with sarcoma, and the toxin led to tumor shrinkage. Although the fact that an infection can induce immunity and eventually tumor regression had been discussed prior to his work, he was the first person who released this result as a report. Therefore, he is known as the father of cancer immunotherapy (Coley, 1891; McCarthy, 2006). By contribution of other scientists, the field has been promoted; many targeted immunotherapies were developed, and lots of them received approval for treatment of different types of cancer.

In concert with the advancement of cancer immunotherapy, it has been figured out that conventional approaches such as the TNM tumor staging system are not sufficient to predict the response to immunotherapy and survival of patients. Therefore, some immune-based strategies such as immunescore and Tumor Immunity in MicroEnvironment (TIME) Classification have been developed (Bruni et al., 2020; Zhang and Chen, 2016; Mlecnik et al., 2011).

To summarize the significant role of the immune system in eradication or progression of tumors, we will review the antitumor and protumor functions of various immune subsets, immune regulation of metastasis, immune based interventions for cancer treatment and prevention, and main immune-based predictive and prognostic biomarkers in this chapter.

Cancer immunosurveillance and immunoediting

The notion of endogenous cancer suppression was proposed by Paul Ehrlich in 1909. He believed that host defense mechanisms are capable of preventing cancer development in most people (Ehrlich, 1908). This hypothesis was supported by Lewis Thomas and Macfarlane Burnet in the 1950s. Lewis Thomas suggested that immunological surveillance mechanisms occur by the recognition of tumor neo-antigens and subsequent elimination mechanisms, similar to the mechanism of homograft rejection (Thomas and Lawrence, 1959). Macfarlane Burnet by consideration of the natural evolution supported the presence of protective mechanisms against tumor cells which can be developed due to genetic alterations in long-lived animals and human. He proposed that immunological responses can eliminate tumor cells because they are activated by antigenic properties of tumor cells attained during malignant transformation (Burnet, 1970). Cancer immunosurveillance theory formed based on these hypotheses and subsequent experimental studies on knockout mice which displayed the roles of various immune components in cancer immunosurveillance (Dunn et al., 2002; Kim et al., 2007).

Aside from the ability of the immune system in eradication of transformed cells, it was revealed that the immune system also plays an essential role in development of a clinically detectable tumor. The cancer immunoediting hypothesis explains the role of the immune system in progression of tumor cells in three phases e.g., elimination, equilibrium, and escape (Dunn et al., 2004). These phases are illustrated in Fig. 1

Immunoediting describes the steps preceding the development of a clinically detectable tumor. Initially, immune effectors eradicate highly immunogenic tumor cells in the elimination phase similar to what happens in cancer immunosurveillance. Although cytotoxic T lymphocytes (CTL) are the key players to recognize and attack malignant cells (Mukherji et al., 1990), both innate and adaptive arms of immunity are essential for eradication of malignant cells in elimination phase; natural killer (NK), CD4⁺ and $\gamma\delta$ T cells are other necessary components in tumor rejection (Mukherji et al., 1990; Krasnova et al., 2017; Terabe and Berzofsky, 2018; Zhao et al., 2018). In equilibrium phase, whose occurrence was questioned for a long time, tumor cells are kept quiescent by both innate and adaptive immunity. In other words, tumor cells with low immunogenicity are selected to survive (Quezada et al., 2011; Wu et al., 2013). In escape phase, survived tumor cells elude the immune system and present a clinically detectable tumor (Dunn et al., 2004). The transformed cells exploit various mechanisms such as downregulation of tumor antigen, impairment of antigen processing and presentation, decreased frequency and activity of immune effectors, increased immunosuppressive components, and alteration of tumor metabolism to escape from the immune system (Corrias et al., 2001; Johnsen et al., 1999; Idos et al., 2020; Schaefer et al., 2005; Huber et al., 2017).

Fig. 1 Cancer immunoediting. The figure displays three phases of cancer immunoediting including elimination, equilibrium, and escape. The Innate and adaptive immune cells contribute to tumor rejection in the elimination phase. Tumor dormancy occurs in the elimination phase under influence of both innate and adaptive immunity. As a result of immunosuppressive microenvironment and dysfunctional T cells, immune evasion occurs in the escape phase.

Tumor antigens

Tumor antigens are the most important markers for the recognition and elimination of tumor cells by CTLs. Tumor antigens mainly are peptides or glycoproteins. They are produced by tumor cells and stay in one of the cellular compartments including the membrane, cytosol, or nucleus. They might also be secreted to the blood stream (Zarour et al., 2003). There are various categories for tumor antigens and they are generally classified into tumor associated antigens (TAA) and tumor specific antigens (TSA). TAAs are normally expressed in healthy tissues but overexpressed or posttranslationally altered in malignant tissues. In contrast, TSAs are exclusively expressed by tumor cells and caused either by mutation or viral oncogenes (Zarour et al., 2003; Feng et al., 2008; Dalet et al., 2011). Based on the origin, there are also other categories of tumor antigens summarized in Table 1.

Initially, tumor antigens were identified by using a mouse tumor-specific CTL which recognized a peptide derived from tumor cells (Lurquin et al., 1989). Indeed, MHC class I molecules on tumor cells present short peptides, which contain 8-10 amino acids originated from mutated, or overexpressed intracellular proteins, to T cells (Vigneron and Van den Eynde, 2011). Nowadays, direct or forward immunology and indirect or reverse immunology are used for identification of tumor antigens. Forward immunology approaches use CTLs isolated from patients and cDNA expression libraries to identify cDNAs encoding CTL epitopes while reverse immunology approaches use an algorithm-based method to predict the binding of a peptide to MHC class I. The later might also predict peptides that are not naturally processed and presented by MHC I molecules to induce T cell response. This disadvantage necessitates validation methods for the candidate peptides (Traversari et al., 1992; Popović et al., 2011).

The identified tumor antigens might be used for screening, diagnosis, monitoring and prediction of prognosis (Even-Desrumeaux et al., 2011). They are also great targets for immune-based interventions such as monoclonal antibodies (mAbs), vaccines, and chimeric antigen receptor (CAR) T cell therapy (Kantoff et al., 2010a; Braendstrup et al., 2020; Cobleigh et al., 1999; Kimura et al., 2013). An ideal tumor antigen for clinical targeting is the one with (1) high immunogenicity, (2) oncogenic function, (3) extracellular expression which makes it accessible for recognition by T cells and immunoglobulins, (4) specificity and (5) high expression level compared to the normal tissue (Zarour et al., 2003; Engelhard et al., 2002; Khong et al., 2004; Kessler and Melief, 2007; Cheever et al., 2009). Overall, ideal tumor antigens can make an appreciable difference in the field of cancer treatment and prevention.

Immune subsets in cancer immunopathology

Various immune cell lineages are present in the tumor microenvironment which contribute to either progression or rejection of tumors. Generally, immune cells with cytotoxic capabilities are involved in tumor rejection while immune cells with suppressive properties foster tumor progression and metastasis. In this section, we will review the functions of various immune subsets in cancer immunopathology.

Dendritic cells (DCs)

Nucleated cells contain the major histocompatibility complex (MHC) class I and can present antigens to CD8+ T cells; however, tumor cells are not potent T cell stimulators. Instead, professional antigen presenting cells (APCs) stimulate CD8+ T cells through cross presentation of tumor antigens i.e., uptake and processing of tumor antigens obtained from dead cells and their presentation to CD8+ T-cells. In addition, APCs contain not only MHC I but also MHC II enabling them to stimulate both CD8+ and CD4+ T cells (Petersen et al., 2010; Joffre et al., 2012; Jongbloed et al., 2010).

Dendritic cells (DCs) originate from myeloid and lymphoid progenitors. Conventional DCs (cDCs) usually originate from myeloid progenitors while CD123+ plasmacytoid DCs (pDCs) originate from both myeloid and lymphoid progenitors (Manz et al., 2001; Rodrigues et al., 2018). DCs might also be differentiate from monocytes and develop monocyte-derived DCs (MoDCs) in inflammatory states (Schlitzer et al., 2015). Generally, pDCs do not perform a strong antigen presentation. They stimulate

Table 1 Categories of tumor antigens.

Category	Characteristics	Example
Oncoviral antigens	Originate from oncogenic viruses, not present in non-infected tissues	HPV E6 and E7 proteins (Kessiss et al., 1993)
Neo-antigens	Mutated or transcriptionally modified peptides, not presented in normal tissues	Mutant PTEN (Keskin et al., 2019)
Cancer testis antigens	Normally expressed by testis and placenta	MAGE-A (van der Bruggen et al., 1991)
Oncofetal antigens	Prominently expressed by fetal tissues	AFP (Wepsic, 1983)
Overexpressed antigens	Expressed by normal tissues overexpressed by tumor cells	HER2 (Slamon et al., 1987)
Differentiation antigens	Lineage specific, expressed by tumor cells and the corresponding normal tissue	Melan-A/MART-1 (Berset et al., 2001)
Retired antigens	Expressed prior to maturity	alpha-lactalbumin (Jaini et al., 2010)
Cancer stem cell antigens	Expressed on cancer stem cells and responsible for recurrence	TLR2 (Conti et al., 2013)

Abbreviations: HPV Human papillomavirus; PTEN Phosphatase and tensin homolog; MAGE-A Melanoma antigen-A; AFP alpha-fetoprotein; HER2 human epidermal growth factor receptor 2; Melan-A Melanoma antigen recognized by T cells; TLR2 Toll-like receptor 2.

expansion of regulatory T cells (Tregs) through the inducible T cell costimulator ligand (ICOSL), and associate with poor outcome in cancer (Aspord et al., 2013; Liu et al., 2019; Villadangos and Young, 2008). Although pDCs produce type I interferons (IFN) exerting antitumor functions, these cytokines can be inhibited in an immunosuppressive tumor microenvironment (TME) (Demoulin et al., 2013). cDCs are classified into cDC1 (CD141+), and cDC2 (CD1c+) subsets. cDC1s contribute to the activation of both cytotoxic CD8+ T cells (through cross-presentation of endogenous antigens) and T helper 1 (Th1) CD4+ cells, while cDC2s mostly activate CD4+ T cells which display an anti-tumor function (Macri et al., 2018; Merad et al., 2013; O'Keefe et al., 2015; Binnewies et al., 2019).

Maturation of DCs is important for their antitumor activities. Immature DCs contain pattern recognition receptors (PRRs) such as Toll-like receptors (TLRs) and cytoplasmic NOD-like receptors (NLRs) which are involved in maturation of DCs by recognition of danger signals or damage-associated molecular patterns (DAMPs) (Khajeh Alizadeh Attar et al., 2018; Saxena and Yeretssian, 2014). Mature DCs express MHCs, chemokine receptors and co-stimulatory molecules (Table 2) (Villadangos et al., 2005; Caux et al., 1994). The chemokine receptor CCR7 on mature DCs plays the main role in the migration of DCs to tumor-draining lymph nodes (TDLN) (Roberts et al., 2016). DCs are also involved in T cell recruitment to the TME through expression of CXC-chemokine ligand 9 (CXCL9)/10 (Spranger et al., 2017).

Cytotoxic activity of CD8+ T cells is the central determinant of tumor rejection. Therefore, CD8+ T cell priming upon cross-presentation of tumor antigens is the key antitumor function of DCs, especially cDC1s the main DC subset accountable for antigen cross-presentation. Three signals are required for this purpose: (i) presentation of tumor antigen on MHC to T cell receptor (TCR), (ii) co-stimulation through specific molecules on DCs and T cells and (iii) secretion of proper cytokines (Wculek et al., 2020). MHC I presents antigens to the TCR on CD8+ T cells while MHC II matches with the TCR on CD4+ T cells. The second signal is performed through co-stimulatory molecules involved in T cell priming, including CD80/CD86-CD28, CD137L-CD137, and ICOSL-ICOS (Table 2) (Chen and Flies, 2013), and The third signal depends on the secreted cytokines. IL-12 is the cytokine required for Th1 differentiation and cytotoxic activity of CD8+ T cells. It is secreted by basic leucine zipper transcription factor ATF-like 3 (BATF3)-dependent cDCs through stimulation of TLRs (Mittal et al., 2017; Nizzoli et al., 2013). IL-12 causes IFN- γ secretion by NK cells and the subsequent reinforcement of IL-12 secretion by cDCs (Hochrein et al., 2000). Signaling through co-inhibitory

Table 2 Co-stimulatory and co-inhibitory molecules on DCs and their counterparts on T cell.

	<i>Expressed by DCs</i>	<i>Counterpart on T cells</i>
Co-stimulatory	CD80	CD28
	CD86	CD28
	ICOSL	ICOS
	CD137L	CD137
	4-1BBL	4-1BB
	OX40L	OX40
	CD70	CD27
	CD40	CD40L
	TL1A	DR3
	GITRL	GITR
	CD30L	CD30
	SLAM	SLAM
	CD48	CD2
	CD58	CD2
	CD155	CD226
	CD112	CD226
Co-inhibitory	CD80	CTLA-4
	CD86	CTLA-4
	PD-L1	PD-1
	PD-L2	PD-1
	VISTA	unknown
	MHC II	LAG-3
	CD31	CD31
	Galectin9	TIM3
	CD112	TIGIT
	CD113	TIGIT
	CD155	TIGIT

Abbreviations: ICOS Inducible T Cell Costimulator; ICOSL Inducible T Cell Costimulator Ligand; TL1A Tumor necrosis factor-like cytokine 1A; SLAM Signaling lymphocytic activation molecule; GITRL Glucocorticoid-induced tumor necrosis factor receptor family-related protein ligand; GITR glucocorticoid-induced TNFR family related gene; VISTA V-domain Ig suppressor of T cell activation; TIGIT T cell immunoreceptor with Ig and ITIM domains; CTLA-4 cytotoxic T-lymphocyte-associated protein 4; PD-1 Programmed cell death protein 1; PD-L1 Programmed death-ligand 1; PD-L2 Programmed death-ligand 2.

molecules on T cells such as CTLA-4 and metabolic alterations namely activation of indoleamine 2,3-dioxygenase 1 (IDO1) which uses tryptophan, a necessary factor for T cell function, are among the barricades of T cell priming (Buchbinder and Desai, 2016; Hwu et al., 2000).

DCs might also show protumor properties and become tolerogenic due to the effect of interleukin-10 (IL-10) or 1 α ,25(O)2D3, a vitamin D3 metabolite (Gur-Wahnon et al., 2009; Ferreira et al., 2015). Tolerogenic DCs with immature or semi-mature characteristics upregulate receptors and ligands such as immunoglobulin like transcript (ILT3) and ILT4 which contain immunoreceptor tyrosine-based inhibitory motifs (ITIMs) and stimulate expansion of the immunosuppressive T cells, regulatory T cells (Treg) (Li et al., 2020; Manavalan et al., 2003).

Tumor cells also contribute to the impairment of antitumor functions of DCs. They express T cell immunoglobulin mucin receptor 3 (TIM3) to prevent the danger signal high mobility group protein B1 (HMGB1) which is involved in the activation of DCs and antigen presentation (Chiba et al., 2012). They produce agonists of liver X receptor- α (LXR α) to inhibit CCR7 necessary for DC migration to TDLN and versican to increase IL-10 and IL-6 and to impair DC functions (Villablanca et al., 2010; Tang et al., 2015).

T-cells

Both conventional T cells containing $\alpha\beta$ TCR and unconventional T cells containing $\gamma\delta$ TCR contribute to tumor rejection. T cells originate from lymphoid progenitors in bone marrow and mainly develop in the thymus. Initially, they are immature cells which express CD3 and either the $\alpha\beta$ or $\gamma\delta$ TCR but not CD4 or CD8. The conventional or $\alpha\beta$ T cells undergo negative and positive selection and most of them with high affinity to self-peptides are eliminated. After selection, TCR rearrangement, and expression of either CD4 or CD8, naïve T cells enter the peripheral blood (Katz and Rabinovich, 2020). It is noteworthy to mention that during selection some subclasses with high affinity to self-peptides including natural killer T cells (NKTs) and Tregs remain (Stritesky et al., 2012). $\gamma\delta$ T cells also undergo negative and positive selection but these processes are not necessary checkpoints for $\gamma\delta$ T cell development. Despite conventional T cells which recognize peptides through a classic MHC-mediated mechanism, $\gamma\delta$ T cells are responsible for classic MHC-independent antigen recognition (Prinz et al., 2006; Jensen et al., 2008). Further differences and functions of these subtypes will be discussed in next sections.

Initially, conventional T cells are naïve and in resting state. They are featured with low cell volume, metabolism, and proliferation rate. IL-7 and a weak baseline function of the TCRs recognizing healthy self-peptides support the proliferation of naïve T cell (Geltink et al., 2018). Following antigen presentation by MHC to the corresponding TCR, clonal expansion and differentiation of naïve T cells occurs, mTORC1 is activated, and the metabolic rate and cell volume increase (Katz and Rabinovich, 2020; Jones and Pearce, 2017). The clonal expansion is performed by sequential asymmetric cell division which produce memory T cells and terminally differentiated effector T cells which might be CD8+ CTLs or CD4+ helper T cells (Arsenio et al., 2015).

In addition to IL-7, other cytokines are also important for activation and proliferation of T cells. IL-2 and IL-4 are also involved in proliferation and survival of T cells. As mentioned, IL-12 is also required for T cell activation upon antigen recognition. A deprivation in these cytokines, for instance, by Tregs, can cause T cell apoptosis (Pandiyan et al., 2007). The development of memory T cells which survive to provide a long-term protection and rapid anamnestic reaction to future stimulations is also dependent on cytokines namely IL-7 and IL-15. IL-7 accounts for the upregulation of Bcl-2, the antiapoptotic protein, to develop memory T cells and IL-15 supports their proliferation. (Kim et al., 2008). Memory T cells are divided into central and effector memory T cells. Effector memory T cells circulate in the blood and non-lymphoid tissues to exert a rapid response to the target antigen while central memory T cells mostly available in lymph nodes can give rise to effector T cells and effector memory T cells (Sallusto et al., 1999).

As mentioned before, the second signal for T cell activation is provided by CD28 which can be expressed by both CD4+ and CD8+ T cells and binds to CD80/CD86 on DCs (Riha and Rudd, 2010). However, CTLA-4 competes with CD28 and exert inhibitory effects through binding to CD80/CD86.

In addition to competition, CTLA-4 exploits further mechanisms to inhibit T cell priming. It mediates endocytosis of CD80/CD86 to suppress their ligation with CD28 and decrease IL-2 production (Qureshi et al., 2011a; Greenwald et al., 2001; Krummel and Allison, 1995). It also disrupts cytoskeleton and through this interferes with antigen presentation by DCs (Schneider et al., 2006). The most important function of CTLA-4 is inhibition of phosphorylation of the CD3 ζ -subunit of the TCR and the adaptor protein linker of activated T cells (LAT) (Lee et al., 1998). CTLA-4 performs this function through SH2 domain-containing tyrosine phosphatase 2 (SHP2) (Marengère et al., 1996). It also uses protein phosphatase 2A (PP2A) to inhibit the downstream molecule of the TCR, extracellular signal-regulated kinase (ERK) (Chuang et al., 2000). CTLA-4 also contributes to development of anergic T cells, by decreasing some transcription factors including activator protein 1 (AP-1), nuclear factor- κ B (NF- κ B) and nuclear factor of activated T cells (NFAT) (Greenwald et al., 2001; Fraser et al., 1999).

CTLA-4 is restored within intracellular vesicles in naïve T cells and can be secreted to the immunological synaptic space to inhibit T cell priming (Linsley et al., 1996). It is also expressed by T cells early after activation to develop T cell anergy (Greenwald et al., 2001). Interestingly, CD4+CD25+ Tregs constitutively express CTLA-4 and whenever present contribute to trans-endocytosis of CD80/CD86 and prevention of co-stimulation (Linsley et al., 1996; Qureshi et al., 2011b). PD-1 is another inhibitory molecule expressed on the surface of T cells in the later steps of immune response. It binds to PD-L1 and PD-L2 its ligands on tumor cells and T cells and advances T cell exhaustion (Prall and Hühns, 2017). PD-1/PD-L1 are expressed during inflammation to make a restricted T cell function and prevent the expansion of inflammatory response (Chen and Han, 2015). However, it is not of interest in the immune rejection of tumors.

Overall, T cells might be dysfunctional through different fates: (i) anergy is the state of T cell inactivity due to the lack of signal 2 or 3, low production of IL-2 and subsequent impaired T cell differentiation. (ii) Exhaustion is the state of T cell dysfunction due to excessive and chronic stimulation with signal 1 or 3, and decreased level of the required cytokines. These effects weaken the effector activity of T cells. (iii) Senescence is the state of stopping the cell cycle which might be caused by aging and short telomere, Tregs, or tumor associated stress. (Wherry and Kurachi, 2015; Crespo et al., 2013; Huff et al., 2019). Stemness is also another fate of T cells which is favorable for tumor destruction. In this state, stem-cell like memory T cells re-establish themselves to produce central and effector memory T cells (Vodnala et al., 2019).

CD8+ CTLs

CD8+ CTLs are the key immune subsets for tumor elimination. Cytotoxic functions of CD8+ T cells against cancer has been revealed by isolation of tumor antigen-specific CTLs in restricted and regressing tumors (Boon et al., 1997; Echchakir et al., 2000). To play their role, CD8+ T cells need to be differentiated and infiltrated into the TME (Nolz, 2015). Naïve CD8+ T cells progress to effector and then to cytotoxic and memory CD8+ T cells upon antigen presentation and secretion of appropriate cytokines (Nolz, 2015). Their recruitment to the TME is dependent on chemokines and chemokine receptors i.e., CXCL9, CXCL10, CXCL11 - CXCR3 and CXCL16 - CXCR6 (Slaney et al., 2014).

To destroy tumor cells, CD8+ CTLs secrete perforin and granzyme as the main direct mechanism of cytotoxicity (Yasukawa et al., 2000). They also can use other cytotoxic pathways including Fas(CD95)/Fas ligand (FasL), TNF- α /TNF receptor 1, and TNF-related apoptosis-inducing ligands (TRAILs)/DR4 or DR5 (Rossin et al., 2019; Martínez-Reza et al., 2017). They induce indirect tumor destruction through secretion of interferon γ (IFN- γ) and tumor necrosis factor- α (TNF- α) (Bossi et al., 2002). After clearance of the diseased cells, T cells undergo apoptosis in the contraction phase (Rossin et al., 2019; Martínez-Reza et al., 2017).

As mentioned before, T cells might become dysfunctional. Chronic weak antigen presentation to TCRs leads to an impaired response known as T cell exhaustion characterized by diminished stimulatory cytokines including IL-2, restricted T cell proliferation, differentiation, and trafficking, increased co-inhibitory molecules such as PD-1, CTLA-4, lymphocyte activation gene 3 protein (LAG-3), and T-cell immunoglobulin domain and mucin domain protein 3 (TIM-3), and decreased cytotoxic activity due to impaired production of TNF- α , IFN- γ , and granzyme b (Wherry and Kurachi, 2015; Maimela et al., 2019).

Tumor cells and immunosuppressive components in TME restrain the anti-tumor function of CTLs as well. Tumor cells prevent T cell infiltration into the TME through various mechanisms including impaired chemokine secretion, tumor angiogenesis and co-inhibitory signaling (Maimela et al., 2019). Immunosuppressive cells also contribute to this state through production of vascular endothelial growth factor (VEGF) transforming growth factor- β (TGF- β), IL-10, CTLA-4, indoleamine 2,3-dioxygenase (IDO), nitric oxide (NO), and reactive oxygen species (ROS) (Gajewski et al., 2006). Regulatory T (Treg) cells and myeloid-derived suppressor cells (MDSC) are the main immunosuppressive cells in the TME and will be discussed in next sections. In addition to immune subsets and tumor cells, other cell lineages such as cancer-associated fibroblasts (CAF) have an effect on the immune response. Interestingly, stromal components including CAFs shape a structure for tumor growth and impede the immunological destruction of tumor cells (Singh et al., 1992). They express fibroblast-activating protein (FAP) to suppress antitumor functions of the immune system (Kraman et al., 2010). They are immunosuppressive, produce IL-6, CXC-chemokine ligand 9 (CXCL9) and TGF β to hinder the antitumor activity of T cells and indicate a poor prognosis in cancer (Qiao et al., 2018; Fearon, 2014).

The infiltration of CTLs to the TME correlates with tumor regression and better clinical outcome. The higher CTLs in the TME the better prognosis in many cancer types including breast and colorectal cancer (Stanton and Disis, 2016; Pagès et al., 2009). Due to the importance of the infiltration and function of CTLs in antitumor immunity, the composition and spatial distribution of CTLs are used for classification of the tumor immune microenvironment (TIME). There are 2 main types of TIME: (i) An infiltrated-excluded (I-E) TIME is defined as a milieu infiltrated with multiple immune cells but a lack of CTLs in the tumor core (Binnewies et al., 2018). In this phenotype, CTLs instead are arranged along the border of the tumor mass and prevented to infiltrate to the tumor core by Ly6C^{lo} F4/80^{hi} tumor-associated macrophages (TAMs) (Beatty et al., 2015). It seems that the I-E TIMEs are not potently immunogenic to destroy tumor cells (Spranger, 2016). Compared to inflamed TIME, it is composed of CTLs with low expression of GZMB (GRZB) and IFNG. The features of low infiltration to the tumor core and low expression of activation markers demonstrate immunologic tolerance (Binnewies et al., 2018). I-E TIMEs are observed in epithelial-originated malignancies including melanoma, colorectal carcinoma (CRC) and pancreatic ductal adenocarcinoma (PDAC) (Herbst et al., 2014; Mlecnik et al., 2016; Ademmer et al., 1998). (ii) An infiltrated-inflamed (I-I) phenotype is the state of a TIMEs with infiltrating CTLs expressing PD-1 as well as tumor cells and immune cells expressing PD-L1. A good example of this TIME is CRC with microsatellite instability high (MSI-H) which associates with higher frequency of neoantigens, PD-1+ CTLs, and a better response to immune checkpoint inhibitors (Binnewies et al., 2018). An infiltrated-TLS TIME is a subtype of I-I TIME which indicates the features of a tertiary lymphoid structure (TLS) at the invasive tumor border. A TLS is a structure resembling lymph nodes composition (Binnewies et al., 2018). It contains DCs, naïve and activated T cells, and Tregs and is a location for activation of immune cells upon inflammation for example after receiving autologous cancer vaccine (Neyt et al., 2012; Lutz et al., 2014). Therefore, infiltration of CTLs to the tumor core is of great importance to predict immunological rejection of tumors.

CD4+ T-helper cells

CD4+ T cells recognize tumor antigen presented on MHC II (König et al., 1992). Helper functions of CD4+ T cells foster antitumor CD8+ CTLs (Borst et al., 2018). It has been demonstrated that the lack of CD4+ T cells leads to tumor progression since CD4+ T

cells improve both the frequency and activity of CD8⁺ CTLs (Marzo et al., 2000; Ossendorp et al., 1998). Through secretion of IL-2, CD4⁺ T cells directly increase differentiation and proliferation of CD8⁺ CTLs (Hor et al., 2015). Tumor-antigen-specific CD4⁺ T cells also foster the infiltration of CD8⁺ T cells to the TME (Wong et al., 2008). By expression of CD40L, CD4⁺ T cells indirectly foster CD8⁺ CTLs. The CD40L on CD4⁺ T cells binds to the CD40 on DCs to propel DCs toward type I subtype capable to prime naïve CD8⁺ T cells (Schoenberger et al., 1998). CD4⁺ T cells also have a role in development and maintenance of CD8⁺ T cell memory. Their presence during CD8⁺ T cell priming is crucial for development of memory T cells (Shedlock and Shen, 2003; Janssen et al., 2003). Tumor antigen-specific CD4⁺ memory T cells can increase the expansion of the cognate CD8⁺ memory T cells as well (Hwang et al., 2007). They also participate in induction of antitumor humoral response. The CD40L on CD4⁺ T cells through binding to CD40 on B cells promote differentiation and maturation of plasma cells, indeed development of antibodies against tumor antigens which correlates with clinical response (Reed et al., 2015).

CD4⁺ T cells can exert direct cytotoxicity as well. Upon induction by various cytokines and transcription factors, CD4⁺ T cells develop different subclasses and exert various effector functions (Fig. 2). The polarization of naïve T cell into Th1, Th9, and Th17 leads to the antitumor functions and Th1 cells are the main antitumor CD4⁺ T cells (Li et al., 1874). Upon polarization toward Th1 cells and under the influence of IL-12, they can secrete IFN γ and TNF α (Kennedy and Celis, 2008). IFN- γ increases antigen presentation through the upregulation of MHC molecules (Dighe et al., 1994). The concurrent presence of these two cytokines foster tumor dormancy and inhibition of escape phase (Müller-Hermelink et al., 2008). CD4⁺ T cells might also perform direct cytotoxic activity similar to what is done CD8⁺ CTLs under special circumstances (Quezada et al., 2010).

CD4⁺ T cells have been identified as a prognostic biomarker in non-small cell lung cancer (NSCLC). It has been revealed that the presence of CD62L^{lo} CD4⁺ T cells which are T-bet⁺ CXCR3⁺ CD27⁺ FoxP3⁺ correlates with the presence of CD8⁺ effector T cells and improved response to PD-1 blockade (Kagamu et al., 2020). It has also been shown that the presence of TERT-specific Th1 CD4⁺ T cells is a prognostic biomarker for NSCLC (Laheurte et al., 2019). Altogether, CD4⁺ T cells are significant agents for tumor rejection.

Tregs

Despite effector CD4⁺ T cells which exert antitumor functions, Tregs are CD4⁺ CD25⁺ T cells which express the FoxP3 transcription factor (Fontenot et al., 2003). They are necessary for maintenance of immune homeostasis and preventing autoimmune diseases. However, this attribute promotes immunosuppression and protumor functions in TME (Sakaguchi et al., 2010a). FoxP3⁺ CD4⁺ T cells are classified to 3 subtypes: CD45RA⁺ FoxP3^{low} CD4⁺ T cells or naïve Tregs, CD45RA⁺ FoxP3^{high} CD4⁺ T cells or effector Tregs which are the main immunosuppressive immune cells, and CD45RA⁺ FoxP3^{low} CD4⁺ T cells or non-Tregs which perform immunostimulatory functions and secrete IFN- γ and IL-17 (Miyara et al., 2009).

The most important immunosuppressive activities of Tregs are mediated through CTLA-4 and IL-2 consumption (Wing et al., 2008). To suppress the immune response, they consume IL-2 via CD25 (the IL-2 receptor α -chain) and degrade ATP (Sakaguchi et al., 2010b). The FoxP3 decreases expression of IL-2 and increases the expression of CTLA-4 and CD25 (Hori et al., 2003). Without CTLA-4, Tregs are not able to perform immunosuppressive functions (Wing et al., 2008). CTLA-4 binds to the CD80/86 molecules

Fig. 2 Polarization of naïve CD4⁺ T cells. Various subtypes of CD4⁺ T cells with distinct functions are developed under the influence of a variety of cytokines and transcription factors.

on APCs with more affinity than CD28. CTLA-4 alongside with CD80/86 moves to Tregs which impairs APC maturation (Walker and Sansom, 2011). Tregs also produce inhibitory cytokines such as IL-35, IL-10, and TGF- β targeting tumor antigen presentation by DCs (Jørgensen et al., 2019). Production of TGF- β by Tregs inhibit antitumor functions of NK cells as well (Ghiringhelli et al., 2005).

Tregs can be derived from both effector and naïve CD4+ T cells and they might also be reversely converted to effector T cells (Tay et al., 2021). In colorectal cancer, it has been shown that there is a population of Tregs with low expression of FoxP3 which are induced by IL-12 and exert antitumor functions. The higher infiltration of this population associated with better prognosis (Saito et al., 2016). Therefore, non-Tregs show antitumor functions despite the effector Tregs which are potent immunosuppressive cells.

Gamma Delta T-cells

$\gamma\delta$ T cells compose around 1-10% of CD3+ T cells in the peripheral blood (Parker et al., 1990). They provide a protective effect on tumors and deficiency of TCR δ chain leads to a higher incidence of malignancy (Girardi et al., 2001). $\gamma\delta$ T cells by expression of the NK cell receptors show the feature of innate immunity and by expression of TCR share the characteristics of adaptive immunity (Melandri et al., 2018). They can recognize TCR-specific tumor antigens. However, despite $\alpha\beta$ T cells, they are not dependent on classic MHC molecules (Katz and Rabinovich, 2020). They use natural killer cell receptors (NCRs) including NKG2D, NKP30, and DNAM-1 to recognize various tumor antigens in an MHC-independent manner (Bonneville et al., 2010; Kabelitz et al., 2020). The cytotoxic function of $\gamma\delta$ T cells is dependent on the activation by ligation of NKG2D and its ligands MHC I-related chain A (MICA), MICB, and UL16-binding proteins 1, 2, and 3 (ULBPs) expressed on cells under stress such as activation of Ras, ultraviolet radiation, and epidermal growth factor receptor (EGFR) signaling (Nausch and Cerwenka, 2008; Shafi et al., 2011). $\gamma\delta$ T cells are in a pre-activated condition and are not dependent on clonal expansion and differentiation (Vantourout and Hayday, 2013). Upon activation, $\gamma\delta$ T cells can directly perform cytotoxicity, secrete perforin, granzyme, chemokines, and Th1 cytokines to exert antitumor functions. They can activate a variety of immune cells including APCs, $\alpha\beta$ T cells and B cells (O'Neill et al., 2020; Nussbaumer and Koslowski, 2019). They also play an APC role to present antigens to $\alpha\beta$ T cells (Meuter et al., 2010).

The most frequent subtype of $\gamma\delta$ T cells consisting more than half of the $\gamma\delta$ T cells in the peripheral blood is V γ 9V δ 2T cells which contain a TCR made by the variable (V) gene V γ 9 and V δ 2 (Hinz et al., 1997; Wesch et al., 1998). V γ 9V δ 2T cells or in short V δ 2 cells perform various functions via recognition of pyrophosphate antigens through butyrophilin-3 subfamily molecules such as BTN2A1 and BTN3A1 (Yazdanifar et al., 2020). They use specific TLRs for costimulation (Pietschmann et al., 2009) and can differentiate into different T helper cells to produce the related cytokines such as IL-4, IL-10, IL-9, or IL-17 (Wesch et al., 2001; Ness-Schwickerath et al., 2010; Peters et al., 2016). They displayed antitumor functions in both solid and hematologic malignancies (Vantourout and Hayday, 2013; Airolidi et al., 2015) and contribute to tumor rejection.

Natural killer T (NKT) cells

NKT cells are another subtype of T cells which are not dependent on the classic MHC molecules. They are among the first immune responders to tumors and rapidly produce cytokines (Terabe and Berzofsky, 2008). They mainly have a protective role against tumor; however, they might also play a protumoral role (Terabe and Berzofsky, 2008). They express T cell receptor (TCR)-CD3 complexes as well as the NK cell receptor CD161 (Godfrey et al., 2010). The invariant NKT (iNKT) or type I NKT cells in human express a semi-invariant TCR, V α 24-J α 18 paired with V β 11 (Lantz and Bendelac, 1994). iNKT cells recognize glycolipid antigens such as α -Galactocylceramide (α -GalCer) the most important glycolipid presented on CD1d. Upon recognition, iNKT cells become activated and produce IFN- γ , perform clonal expansion, and stimulate other immune cells (Lam et al., 2017). iNKT cells are able to perform direct tumor destruction; however, they mainly activate other cytotoxic cells (Metelitsa et al., 2001; Crowe et al., 2002). The antitumor activity of NKT cells is dependent on endogenous IL-12 (Smyth et al., 2000). iNKT cells by expression of CD40 binding to CD40L on immature DCs as well as IFN- γ production have a role in the maturation of DCs which produce IL-12. IL-12 gives rise to the production of IFN- γ and IL-2 by iNKT cells. iNKT cells can activate other tumor killer cells including NK cells and CD8+ T cells through IL-2 and IFN- γ production (Terabe and Berzofsky, 2008; Metelitsa et al., 2001). IFN- γ has an antiangiogenic role in tumor immunity as well (Hayakawa et al., 2002). Production of Th1 cytokines is another antitumor activity of iNKT cells (Terabe and Berzofsky, 2008).

There is another type of NKT cells, Type II NKT cells which do not express the CD1d-restricted TCR, express more variable TCRs, and foster tumor outgrowth. Type II NKT cells produce IL-13, which provoke production of TGF- β by myeloid cells which in turn suppress CTL functions (Terabe et al., 2000, 2003). Moreover, thymic NKT cells show less antitumor immunity than liver NKT cells due to the production of IL-4 (Crowe et al., 2002). Therefore, NKT cells consisting of type I and II exerts antitumor and protumor functions, respectively.

Natural killer (NK) cells

In addition to T cells, there is a key agent from the innate immunity responsible for tumor rejection (Deng et al., 2015). Natural killer (NK) cells originate from the common lymphoid progenitor and undergo the "education" process in which their immunoreceptor tyrosine-based inhibitory motifs (ITIMs) recognize MHC I to become licensed ie, recognize healthy cells expressing MHC I

and do not destroy them (Bauer et al., 1999). NK cells recognize malignant and virus-infected cells in the pattern of missing self and induced self (Wu et al., 2020). Therefore, NK cells are necessary for tumor killing since downregulation of MHC I by tumor cells is one the escape mechanisms to flee from the CD8+ cytotoxicity (Bauer et al., 1999). NK cells do not contain TCR or CD3 and utilize the NKG2D receptor to recognize tumor cells expressing the ligands including MICA, MICB, and ULBPs (Eagle and Trowsdale, 2007; Smyth et al., 2005). Transcription factors namely Nfil3, Id2, Tox, EOMES and T-bet as well as cytokines including IL-2 and IL-15 are necessary for the development, maturation and function of NK cells (Wu et al., 2020). NK cells are CD3-CD56+ cells and, based on the CD56 expression, are classified into CD56bright and CD56dim subtypes. CD56 is an important molecule for the differentiation and cytotoxicity of NK cells and is necessary for the development of CD56dim which is finally matured NK cell and the main subset of antitumor NK cells in the peripheral blood (Ferlazzo et al., 2004). However, CD56bright NK cells can also perform antitumor activities upon stimulation with IL-2 or IL-15 (Ferlazzo et al., 2004; Wagner et al., 2017).

NK cells exert direct cytotoxic functions through perforin and TRAIL to destroy tumor cells (Takeda et al., 2001). Upon expression of IL-15 and its receptor IL-15 receptor α in the TME, the infiltration and induction of cytotoxic granulated NK cells occurs (Liu et al., 2012). They are capable to produce cytokines including IFN- γ , TNF, and GM-CSF (Fehniger et al., 1999). The function of NK cells depends on the activating and inhibitory receptors. The activating receptors include NCRs, integrins, and cytokine-binding receptors (Wu et al., 2020). Inhibitory receptors include MHC I-specific receptors including killer cell immunoglobulin-like receptors (KIRs), leukocyte immunoglobulin-like receptors (LILRs), killer lectin-like receptors (KLRs), and MHC-I non-related receptors namely NKG2A (Wu et al., 2020).

Myeloid-derived suppressor cells (MDSCs)

Myeloid-derived suppressor cells (MDSC) are immature myeloid-lineage cells which play an immunosuppressive role in the TME. They foster tumor progression and immune escape, as well as metastasis through angiogenesis, formation of pre-metastatic niche, and epithelial-mesenchymal transition (EMT) (Li et al., 2017; Sceneay et al., 2013; Toh et al., 2011). They suppress the antitumor activities of T cells by induction of T cell dysfunction and inhibition of T cell activation, expansion, and infiltration. They decrease the production of IL-12 and prevent CD8+ T cell infiltration which is reversible by IL-12 treatment (Steding et al., 2011). MDSCs disturb T cell trafficking through increased production of reactive nitrogen species (RNS) and expression of a disintegrin and metalloproteinase 17 (ADAM17) to destroy the CD62L on T cells (Hanson et al., 2009a, b; Molon et al., 2011).

There are two subtypes of MDSCs: (i) granulocytic or polymorphonuclear MDSCs (PMN-MDSCs) which are CD11b⁺CD14⁻CD15⁺ or CD11b⁺CD14⁻CD66b⁺ and mimic neutrophils. (ii) monocytic MDSCs (M-MDSCs) which are CD11b⁺CD14⁺HLA-DR⁻/lowCD15⁻ cells and similar to monocytes. Both subtypes can be involved in the proliferation and invasiveness of tumor cells (Bronte et al., 2016).

MDSCs can inhibit antigen-specific T cell response through production of short-lived substances i.e., reactive oxygen species (ROS) and peroxynitrite (PNT). PNT is a potent oxidant which impairs T cell function by nitrating the TCR complex and Tyr394 of lymphocyte-specific protein tyrosine kinase (LCK), a tyrosine kinase involved in TCR signaling (Nagaraj et al., 2007; Feng et al., 2018). Through this alteration the ability of MHC to bind and present tumor antigens to T cells decreases (Lu et al., 2011). Production of ROS and subsequent decreased expression of T-cell receptor (TCR) ζ -chain is another mechanism by which MDSCs impair the function of antigen-specific T cell (Kusmartsev et al., 2004). This mechanism is dependent on the close contact of MDSCs and T cells. MDSCs provide this close contact with T cells by expression of MHC I and presentation of tumor antigen (Nagaraj et al., 2007). There is some evidence showing that MDSCs are able to hamper the function of CD8+ T cells which are only specific for the antigen presented by themselves but no other antigens (Nagaraj et al., 2010).

MDSCs are also able to block non-specific T-cell response. They produce long-lived cytokines, iNOS and arginase 1 (ARG1) for this purpose (Kumar et al., 2016). MDSCs produce inducible nitric oxide synthase (iNOS) to provide nitric oxide (NO). NO inhibits T cell proliferation through the blockade of Jak/STAT5 pathway as well as antigen presentation by DCs (Markowitz et al., 2017; Bingisser et al., 1998). NO is a factor provoking T cell apoptosis as well (Wang et al., 2010). NO also interferes with T cell trafficking by decreasing E-selectin (Gehad et al., 2012). MDSCs decrease the essential amino acids for T cell activity. By expression of ARG1, they hamper L-arginine and ultimately CD3 ζ -chain of the TCR complex (Rodríguez and Ochoa, 2008). By importing cystine but not releasing cysteine, MDSCs deplete cysteine, another amino acid vital for T cell activity (Srivastava et al., 2010). MDSCs produce adenosine which impairs T cell functions (Ryzhov et al., 2011). They produce PD-L1 which binds to the PD-1 on T cells and induce T cell anergy (Weber et al., 2018). They can also impair the CD4+ T cell function if they present a sufficient level of MHC II (Nagaraj et al., 2012). It has also been shown that they also inhibit IFN- γ secretion from CD4+ tumor specific T cells (Chalmin et al., 2010).

MDSCs produce various cytokines namely IL-6, IL-10, and TGF- β (Chandra and Gravekamp, 2013). MDSCs produce the majority of IL-10 in the TME, and there is a correlation between the number of MDSCs, the level of IL-10, and cancer progression (Arihara et al., 2013; Zhang et al., 2015). IL-10 inhibits the activity of DCs and T cells and provokes Treg response. MDSCs produce TGF- β which hampers the function of T cells, NK cells, and NKT cells (Yang et al., 2020). They provoke induction and trafficking of Tregs; the cytokines TGF- β and IL-10 are involved in the induction and the CCR5 ligands CCL3, CCL4, and CCL5 are the main factors for Tregs infiltration (Huang et al., 2006; Schlecker et al., 2012). By and large, MDSCs exploit a variety of mechanisms to hinder the T cells functions.

Tumor-associated macrophages (TAMs)

Macrophages are classified into M1 and M2 subtypes which exert antitumor and protumor functions, respectively. IFN- γ , tumor necrosis factor (TNF), lipopolysaccharide, and GM-CSF participate in development of classically activated or M1 macrophages while inhibitory cytokines including IL-4, IL-10, IL-13, and M-CSF are involved in development of alternatively activated or M2 macrophages (Quatromoni and Eruslanov, 2012; Orecchioni et al., 2019). M1 macrophages exert antitumor functions. They produce proinflammatory cytokines namely IL-1, IL-6, IL-12 and TNF, toxic substances including RNS and ROS, present tumor antigens, and foster a Th1 response (Petty and Yang, 2017). M1 macrophages foster the activation and infiltration of effector T cells through expression of CXCL9, CXCL10 and CCL5 (Mantovani et al., 2013). They also induce ADCC and can perform a direct cytotoxicity by production of cathelicidin (Bruns et al., 2015). M2 macrophages produce IL-10 and TGF- β , COX-2 derived prostaglandin E2 (PGE2), CD206, and CD163 for suppression of T cell responses and CCL2, CCL17 and CCL22 for infiltration of Tregs to TME (Mantovani et al., 2013; Curiel et al., 2004; Ge and Ding, 2020). TAMs are a group of macrophages which exert protumor functions similar to M2 macrophages. However, a distinct subtype might not be attributed to TAMs only by markers; other determinants such as function, milieu, and progression of malignancy should be taken into consideration (Biswas et al., 2006; Nasrollahzadeh et al., 2020).

The high frequency of TAMs in TME is an indicator of poor prognosis. They are involved in angiogenesis and prevention of T cell recruitment (Tsutsui et al., 2005; Dannenmann et al., 2013). They produce different angiogenic stimuli including VEGF, PDGF and bFGF, and other matrix metalloproteinase (MMP) and other molecules which support EMT. They foster establishment of cancer stem cells by production of various cytokines such as TNF- α , IL-6, and EGF (Petty and Yang, 2017). Overall, TAMs mainly support progression of tumors.

Immune regulation and metastasis

Metastasis is a state of tumor cell dissemination from the primary site to the secondary one(s). After growth, tumor cells migrate and invade the surrounding tissue through epithelial-to-mesenchymal transitions (EMTs) and pass into the blood or lymphatic vessels (intravasation), move and survive there, leave the vessels (extravasation), adhere to the secondary site and proliferate there (Guan, 2015; Pearson, 2019). Some immune subsets can prevent metastasis and some contribute to metastasis in different phases (Blomberg et al., 2018). In this section, we will review the dual role of the immune system in cancer metastasis.

Remodeling of ECM is performed by various immune cells (Lu et al., 2012). The ECM remodeling leads to tumor cell invasion through structural alteration of the surrounding tissue, and spread of the growth factors and signaling molecules necessary for tumor progression (Ghajar and Bissell, 2008; Cox and Erler, 2011). In addition to CAFs, immune cells including TAMs, tumor associated neutrophils (TANs) and mast cells are involved in ECM remodeling by secretion of proteases (Gocheva et al., 2010; Nozawa et al., 2006; Ribatti et al., 2003). Bregs also stimulate the production of MMPs by tumor cells and contribute to ECM remodeling (Ou et al., 2015). ECM remodeling is among the early required steps for metastasis.

Angiogenesis and lymphangiogenesis are vital for metastasis both as a channel for migration and as a provider of factors required for tumor survival (Zetter, 1998; Achen et al., 2005; Mazzone et al., 2009). The formation of new blood and lymphatic vessels is also modulated by immune cells (Christiansen and Detmar, 2011; Bruno et al., 2014). Angiogenesis correlates with the frequency of TAMs, Tregs, and mast cells, which produce VEGFA (Leek et al., 1996; Zidlik et al., 2015; Yano et al., 1999; Esposito et al., 2004). Hypoxia which is induced by the growing tumor is one of the factors stimulating angiogenesis (Mazzone et al., 2009). It also attracts TAMs, which produce VEGFA (Ramanathan et al., 2003). IL-17 produced by Th17 is the other inducer of the production of VEGF by tumor cells (Pan et al., 2015). Also, the ECM remodeling modulating enzymes such as MMPs make a loose ECM releasing the matrix-bound VEGF (Lee et al., 2005). Through the abovementioned mechanisms, tumor cells and immune cells contribute to the formation of vessels necessary for metastasis.

Intravasation, survival in the vessels, and extravasation are necessary steps undertaken by tumor cells to migrate into a secondary site. TAMs are involved in intravasation of EGFR+ tumor cells. It has been shown that IL-4/IL-13-activated TAMs produce EGF under the influence of colony-stimulating factor-1 (CSF-1) which is secreted by tumor cells (DeNardo et al., 2009; Wyckoff et al., 2004). The production of IL-4 by CD4+ T cells is also prometastatic since IL-4 regulates macrophage phenotype and inhibit antitumor activities (Qian et al., 2011). Circulating tumor cells (CTCs) must survive various threats including immune destruction, high blood flow shear stress, and anoikis in the challenging environment of vessels (Fu et al., 2016; Liotta and Kohn, 2004; Labelle and Hynes, 2012). NK cells, T cells, and liver-resident macrophages are involved in immune destruction of CTCs (Santos et al., 2014; Ye et al., 2017; Denève et al., 2013). Other cells however support CTC survival. For example, Tregs produce the receptor activator of nuclear factor- κ B ligand (RANKL) and platelets establish a fibrin clot to protect CTC from destruction by immune cells (Tan et al., 2011; Palumbo et al., 2005). CTCs also exploit other approaches to survive. They upregulate CD47 the anti-phagocytic molecule (Steinert et al., 2014), produce HLA-G a driver of immunosuppression (König et al., 2016), and their presence associate with the expression of FAS on T cells which promote T cell apoptosis (Gruber et al., 2013). Myeloid cells also perform prometastatic functions by ingestion of the dying tumor cells and hiding their antigen from DCs (Borghaei, 2015).

For extravasation, tumor cells require to adhere to the endothelium, a process which is supported by some immune cells including neutrophils, and metastasis-associated macrophages or the very inflammatory monocytes (Cools-Lartigue et al., 2013; Qian et al., 2009a, 2011). Neutrophils by production and release of neutrophil extracellular traps (NETs) insulate tumor cells and

induce their invasion and migration into the secondary site (Cools-Lartigue et al., 2013; Park et al., 2016). The adhesion of tumor cells is mediated through the ligation of intercellular adhesion molecule 1 (ICAM-1) on tumor cells with the integrin CD11b on neutrophils (Spicer et al., 2012) as well as the formation of fibrin clot, activation of TGF β -dependent pathways, and releasing ATP-containing granules by platelets (Stegner et al., 2014; Labelle et al., 2011; Schumacher et al., 2013). Inflammatory monocytes also contribute to extravasation. They increase vascular permeability by production of VEGF and provide mechanical help for extravasation (Qian et al., 2011, 2009b).

Based on the “seed and soil” hypothesis, tumor cells do not incidentally metastasize to an organ. There are some intrinsic factors such as expression of specific chemokines on tumor cells which direct them to secondary sites expressing the cognate ligands, and extrinsic factors such as immune and stromal cells which prepare the secondary site or (pre)metastatic niche (Paget, 1989; Müller et al., 2001; Doglioni et al., 2019). Immunosuppression is important for making a (pre)metastatic niche. Among immune cells, immature myeloid cells are recruited from the bone marrow (bone marrow-derived cells [BMDCs]), to establish the (pre-)metastatic niche (Jablonska et al., 2017). Tumor-derived factors induce recruitment of BMDCs and tumor cells as well as preparing the secondary site for their arrival (Erler et al., 2009a; Hiratsuka et al., 2008). The infiltration of myeloid cells alters the local environment of the secondary site to a one with enhanced angiogenesis, vascular permeability, inflammation, immunosuppression, and ECM remodeling (Liu and Cao, 2016). Neutrophils, macrophages and fibroblasts are the major supporters of tumor cell infiltration and extravasation in the (pre)metastatic niche by angiogenesis and ECM remodeling. They produce proangiogenic factors such as Bv8 (Kowanetz et al., 2010) and ECM remodeling factors, such as fibronectin and lysyl oxidase (LOX) (Erler et al., 2009b; Yamamura et al., 2015). Neutrophils might show either prometastatic or antimetastatic functions (Wculek and Malanchi, 2015; Granot et al., 2011). Prometastatic neutrophils can be developed by IL-17 produced by $\gamma\delta$ T cells. These immunosuppressive neutrophils suppress the activity of CD8+ T cells to foster metastasis in early steps (Coffelt et al., 2015). They also support metastasis by production of leukotrienes helping colonization of tumor cells in the secondary site (Wculek and Malanchi, 2015). On the other hand, to prevent metastasis to the secondary site, CD103+ DCs in the secondary site activate CD8+ T cells and inhibit metastasis (Roberts et al., 2016; Headley et al., 2016).

Immune-based interventions for cancer treatment and prevention

Upon understanding of the antitumor and protumor functions of the immune system, various therapeutic approaches have been developed to hinder the barricades of an effective tumor rejection. The majority of these approaches have been assessed in clinical trials and due to the improved clinical outcomes received approval for treatment or prevention of cancer from the US Food and Drug Administration (FDA). However, some of them have yet to be optimized (Keshavarz-Fathi and Rezaei, 2019a, 2021). Herein, we will provide a quick review on the advancement of immune-based interventions for cancer treatment and prevention.

Nonspecific immunomodulators are among the first modalities evaluated for cancer treatment. IL-2, a cytokine predominantly produced by CD4+ T cells has a significant function in the proliferation and activity of T cells (Valle-Mendiola et al., 2016). High-dose IL-2 was approved for the treatment of metastatic renal cell carcinoma and melanoma; however, the monotherapy is not desired since IL-2 participates in expansion of Tregs too (Choudhry et al., 2018). Nowadays, it is mostly used for combination therapy (Razavi et al., 2021). TLR agonists another drug of this class are used for different purposes. They are effective vaccine adjuvants (Keshavarz-Fathi and Rezaei, 2019b) and are potent modalities for treatment and prevention of cancer. For instance, Bacillus Calmette-Guérin (BCG) a TLR2 agonist has been approved for treatment of superficial bladder cancer (Morales and Nickel, 1986), and imiquimod a TLR7 agonist has been approved for immunoprevention of skin squamous cell carcinoma (SCC) (Swanson et al., 2014).

To block the activity of molecules contributing to tumor progression and invasion, monoclonal antibodies (mAb) have been developed. The molecules CD20, HER2, VEGF, EGFR, SLAMF7, CD38, and RANKL are among the targets toward which mAbs have been showed improved clinical outcomes and approved for cancer treatment (Grillo-Lopez et al., 2000; Goldenberg, 1999; Hurwitz et al., 2004; Cunningham et al., 2004; Lonial et al., 2015; Usmani et al., 2015). By addition of a linker and a cytotoxic agent to mAbs, antibody–drug conjugates (ADCs) are constructed which destroy tumor cells expressing the target antigen. ADCs targeting CD22, CD30, and CD33 for hematologic malignancies and an ADC targeting HER2 for breast cancer have been approved (Kantarjian et al., 2016; Connors et al., 2018; Amadori et al., 2016; Verma et al., 2012). Recently, bispecific Abs (BsAbs) which have scFv against both tumor markers and CD3 have been used to engage tumor cells and T cells. They have been approved for treatment of acute lymphoblastic leukemia (ALL) (Kantarjian et al., 2017). mAbs, ADCs, and BsAb are interesting modalities for cancer treatment and are rapidly growing.

Vaccines have been primarily used for prevention of infectious diseases; however, they are interesting modalities with desirable safety profile and long-term protection for treatment and prevention of cancer. Various constructs of vaccines including whole tumor cell, peptide, APCs, mRNA, and DNA have been evaluated and demonstrated improved antigen presentation and CTL response (Keshavarz-Fathi and Rezaei, 2019a, 2021). However, only one APC vaccine which showed improved overall survival in an advanced clinical trial has been approved for prostate cancer (Kantoff et al., 2010b). Due to the advantages of cancer vaccines, their effectiveness, and the recent approval of an mRNA vaccine for COVID-19, there is a hope to rapidly promote cancer vaccines specially mRNA vaccines (Miao et al., 2021).

Immune checkpoint Inhibitors (ICIs) another type of antibodies are directed against inhibitory molecules such as PD-1, PD-L1, CTLA-4, LAG-3, and TIM-3. The PD-1 inhibitors received approval for treatment of many solid tumors including melanoma, lung,

colorectal, renal, bladder cancer, hepatocellular carcinoma, and SCC (Keshavarz-Fathi and Rezaei, 2019a; Weber, 2015; Borghaei, 2015; Overman et al., 2017; Motzer, 2015; Sharma et al., 2017; El-Khoueiry et al., 2017; Kudo et al., 2019; Ahmed et al., 2019), as well as a hematologic malignancy Hodgkin lymphoma (Ansell et al., 2015; Younes et al., 2016). An anti-PD1 Ab is also being evaluated in an ongoing clinical trial for treatment of oral proliferative verrucous leukoplakia (OPVL), indeed prevention of oral SCC (NCT03692325). The PD-L1 inhibitors received approval for treatment of several solid tumors including lung, breast, urothelial, and renal cancer (West et al., 2019; Schmid et al., 2018, 2019; Balar et al., 2019; Motzer et al., 2019). The antibody against CTLA-4 also received approval for treatment of colorectal cancer and melanoma (Eggermont et al., 2015; Overman et al., 2018). Other ICIs directed against LAG-3 and TIM-3 are under evaluation in early clinical trials (NCT02061761, NCT03066648). ICIs are promising interventions which showed significant improvement of survival in patients with cancer; however, resistance to ICIs and their immune-related adverse effects can restrict their usage.

Adoptive cell therapy (ACT) is an immunotherapeutic method which is based on transferring autologous or allogeneic immune cells such as T cells, NK cells, and macrophages to empower antitumor cytotoxicity. Chimeric antigen receptor (CAR) T cell therapy a subtype of ACT equips T cells to 3 main components including a scFv to recognize tumor antigens, the CD3 ζ for signal transduction and a costimulatory molecule such as CD28 and/or 4-1BB (Hosen, 2020; Boyiadzis et al., 2018). It has been approved for treatment of hematologic malignancies including ALL, large B-cell lymphoma, multiple myeloma, and follicular lymphoma in recent years (Maude et al., 2018; Schuster et al., 2019; Munshi et al., 2021) (NCT03105336). CAR macrophages and CAR NK cells are also being evaluated in early clinical trials (NCT04660929, NCT00995137, NCT02944162). Tumor-infiltrating lymphocyte (TIL) therapy is another subtype of ACT in which the T cells infiltrated to the TME are isolated from the patient, activated, expanded and re-infused to the patient. If the isolated T cells are equipped with a new TCR, the approach is known as engineered TCR therapy (Linnemann et al., 2011). CAR T cell therapy and other ACTs are a major breakthrough in immunotherapy for cancer especially hematologic malignancies. They have faced some challenges for solid tumors and yet to be optimized.

Immune-based biomarkers for cancer

Various immune-based biomarkers are used for prediction of prognosis as well as response to immunotherapies. The importance of the TIME in cancer prognosis has recently gained attention. It has been demonstrated that the immune contexture of tumors is indicative of response to treatment and patient survival. Interestingly, a preexisting adaptive immune response in TME associates with a better response to immunotherapy. Therefore, to consider the effect of T cell infiltration to the TME, the immunescore developed (Bruni et al., 2020; Galon et al., 2014). It has been reported that the immunescore surpasses the classic tumor-node-metastasis (TNM) staging system as a prognostic biomarker in CRC (Mlecnik et al., 2011). The immunescore was defined as the frequency of two lymphocyte populations including CD3+ T cells, CD8+ CTLs, and CD45RO+ memory T cells (CD3/CD8, or CD3/CD45RO, or CD8/CD45RO) in the core of the tumor (CT) and the invasive margin (IM) of the tumor (Pagès et al., 2009). It is assessed by immunohistochemical methods and ranges from 0 to 4 which respectively indicate low densities and high densities of both cell types in the CT and IM (Lanzi et al., 2020). Immunescore is a powerful prognostic biomarker for disease-free survival and overall survival in CRC (Pagès et al., 2018).

The immune contexture of tumor can be classified based on other markers. Since the blockade of PD-1/PD-L1 has been a major breakthrough in cancer treatment but some patients do not respond to this intervention, determining the responders is of great importance. It has been revealed that tumor-infiltrating lymphocytes (TILs) and the expression of PD-L1 molecule on T cells are significant biomarkers (Zhang and Chen, 2016; Brahmer et al., 2012; Topalian et al., 2012; Tumei et al., 2014). Accordingly, tumors might display 4 possible TIME classifications including T1 (PD-L1-, TIL-), T2 (PD-L1+, TIL+), T3 (PD-L1-, TIL+), and T4 (PD-L1+, TIL-) (Zhang and Chen, 2016; Taube et al., 2012). Interestingly, there is a correlation between TIL and PD-L1 expression because the production of IFN- γ by T cells, which occurs upon their tumor antigen recognition, provoke the expression of PD-L1 on nucleated cells including T cells (Taube et al., 2012). It is predicted that T2 tumors with high TIL and PD-L1 expression are great responders to the therapy by PD-1/PD-L1 blockade. These tumors contain high level of TIL but are unarmed due to the expression of PD-L1. The majority of tumors are nonresponders to anti-PD therapy. They are either T1 or T4 ie, tumors without TIL. T4 tumors express PD-L1 because of the activation of oncogenic pathways. Several reasons including impaired tumor antigen presentation and immunosuppressive components underlie the lack of TIL (Taube et al., 2012; Parsa et al., 2007). However, some modalities such as local radiation, cryotherapy, and local oncolytic viruses can compromise this state and enhance the tumor antigen shedding and presentation. Likewise, immunotherapies such as vaccines, adoptive T cell therapy, and CTLA-4 blockade can also improve the filtration of TIL (Gupta et al., 2012; Waitz et al., 2012; Luo et al., 2020; van der Burg, 2018; Chruściel et al., 2020). T3 tumors contain TIL but do not express PD-L1 probably due to the lack of IFN- γ secretion by T cells (Sanmamed and Chen, 2014). Upon administration of OX-40 or 4-1BB agonists, T cell tolerance could be reversed. In this case, T3 tumors can turn into T2 tumors which are good responders to PD-1/PD-L1 blockade (Zhang and Chen, 2016). Altogether, the TIME classification can assist the prediction of response to PD-1/PD-L1 blockade. However, since only small slides of the tumor are assessed to detect PD-L1 expression and TIL, novel technologies are warranted to obtain more comprehensive data.

As explained, TIL and PD-L1 expression are the main predictive biomarkers of response to PD-1/PD-L1 blockade. There are also other immune-based biomarkers for prediction of response to ICIs; heterogeneity in the HLA genes, expression level of CTLA-4 and PD-1 on TILs, expression of immune-related genes such as *IFNG* and *GZMB*, and neutrophil to lymphocyte ratio (NLR) are some

examples (reviewed in Mahdavi Sharif et al., 2021). Altogether, exploiting immune-based and other biomarkers is recommended to specify patients benefiting from immune-based interventions.

Conclusion

The immune system has a significant role in determining suppression or progression of tumors, and immune escape is one of the hallmarks of cancer. A comprehensive understanding of the antitumor and protumor functions of various immune subsets led to development of immune-based interventions for treatment and prevention of cancer. Based on the improvement of overall survival and disease-free survival of patients, the majority of interventions have been approved for cancer treatment. However, some of them such as vaccines have failed to show a dramatic clinical response and resistance was developed to ICIs. To overcome the challenges, immunosuppressive phenotype of advanced cancers needs to be inhibited and predictive biomarkers especially immune-based biomarkers should be exploited to include the subgroups of patients benefiting from the treatment.

Glossary

Anaerobic A condition in which there is no oxygen present.

Cariogenesis The generation of tooth decay.

Colonization The growth of a microorganisms after it has accessed host cell tissues.

Commensal Opportunistic microorganisms that reside on outer surfaces and inside the human body that do not cause infections unless dysbiosis occurs.

Dental biofilm A community of microorganisms adhere to a solid surface in an intercellular matrix composing of saliva, gingival crevicular fluid and bacterial products. Exopolysaccharides are produced by the present bacteria maintaining integrity and protect the cells from antimicrobials and harmful agents.

Dental caries Tooth decay.

Dimorphic Microorganisms able to occur as two separate forms. *Candida albicans* can grow as both yeast and filamentous cells.

Disease A disorder of structure or function in organism, especially one that produces specific symptoms or that affects a specific location and is a direct result of physical injury.

Dysbiosis An imbalance between microbial communities within the host.

Enteric virus A virus that resides within the GI tract.

Gastric fluid The acidic fluid secreted by glands in the stomach to aid digestion.

Genera A taxonomic classification that falls below family.

GI Tract Gastrointestinal tract.

Goblet cells Cells found within the respiratory and intestinal tracts that secrete mucins.

Host An organism that harbors a parasite.

Infection The growth of microorganisms in a host that results in eliciting of a immune response.

Monosaccharides Simple sugars forming the basis of carbohydrates.

Mucins A glycoprotein component of mucus.

Mucus Soluble glycoproteins secreted by epithelial cells that coat the mucous membranes.

Mycobiome The fungal component of the microbiome.

Next Generation Sequencing (NGS) Next-generation sequencing.

Normal microbial flora The microorganisms found in association with healthy host tissues.

Pathogen A microorganism that causes disease in a host.

Phyla A taxonomic classification that falls below kingdom.

Pyrosequencing Method of DNA sequencing that detects the order of nucleotides using sequencing by synthesis, revealing the genetic code of a section of DNA.

Stomach Ulcer A form of peptic ulcer disease that present as open sores within the stomach lining.

Symbiosis A mutually beneficial interaction between two organisms.

The commensal microbiome

The commensal microbiome contributes to nutrition, energy and a healthy immune response in humans (Littman and Pamer, 2011) (Fig. 2). Microbes will occupy a niche in which they persist and survive in a mutually beneficial state; however, dysbiosis may result in proliferation of pathogenic microorganisms. An example of this is growth of the Gram positive spore former *Clostridioides difficile* which proliferates when the commensal gut microbiome is altered by the use of broad spectrum antibiotics (Leffler and Lamont, 2015).

Commensal microbial communities are often complex in nature and have thus presented as a challenge to study (Malla et al., 2019). The human gut microbiome for example has been most widely studied through fecal analysis via in vitro culture of single microbial species within the laboratory (Scanlan and Marchesi, 2008). However, standard culture techniques are limited when analyzing the microbiome as many microorganisms have yet to be grown in culture, and their optimal growth conditions remain unknown. The advent of culture-independent approaches, such as metagenomic sequencing, has significantly enhanced our understanding of host microbiome interactions.

Initial studies examined the presence of the 16S ribosomal RNA genes which are suitable conserved sequence for species identification (Madigan et al., 2008). However, advanced sequencing technologies such as next generation sequencing (NGS) have enabled comprehensive study of the environmental and human microbiome. The most notable is the NIH Human Microbiome Project (Peterson et al., 2009; NIH, 2016 <https://www.hmpdacc.org/hmp/>) These include, but are not limited to, metagenomic sequencing of the skin microbiome and the gut microbiome, where whole genome shotgun sequencing could be undertaken (Weinstock, 2012). We are now in an era where sequencing is becoming commonplace to analyze microorganisms, even in real time via the Oxford Nanopore using short read sequencing data (Moss et al., 2020).

The normal microbiota of the skin

The human skin is a physical barrier that prevents invasion by pathogenic microorganisms or any foreign elements. The normal microbiota of the skin comprises beneficial bacteria, viruses and eukaryotes such as fungi and arthropods which exist as commensals in either transient or residential population (Grice and Segre, 2011). The colonization sites of the skin are either dry, moist or sebaceous areas; all of which have varied microbial populations that play key roles in preventing pathogens from infecting the skin. This can be related to the pH and/or moisture content of areas of the skin, where the pH is between 5.3 and 6.5 (Neugent et al., 2020) (Fig. 3).

Fig. 1 The human body. The skin, oral cavity, respiratory system, urogenital tract and gastrointestinal tract (GI Tract) are covered within this chapter. Created using Biorender (2021). <https://app.biorender.com/user/signin>.

However, when the barrier is broken, the balance between commensal microbiota and the invading pathogens is disturbed which can lead to skin infections (Madigan et al., 2008). The skin microbiome is known to harbor a great variety of microorganisms.

Bacteria

Analysis of skin samples via culture-based methods has found that Gram positive bacteria are the most common commensals. These include those of the genus *Staphylococcus* (e.g., *Staphylococcus aureus*, *Staphylococcus epidermidis*), *Streptococcus* (*Streptococcus pyogenes*), *Propionibacterium* (*Cutibacterium acnes*) and *Corynebacterium*. However, through 16S rRNA gene phylotyping a greater diversity of microbiota has been found including Actinobacteria, Firmicutes, Proteobacteria and Bacteroidetes (Byrd et al., 2018). *Propionibacterium* has been found to colonize sebaceous sites; *Corynebacterium* in moist sites and a mixture of Proteobacteria and Actinobacteria are mostly found on dry skin sites. Gram negative bacteria such as *Escherichia coli* do not usually grow on the skin; however, they are often found in skin flora samples due to occasional fecal contamination of the skin via feces. Gram positive microorganisms are better able to colonize these dry skin environments compared to their counterparts and thus out compete Gram negatives (Percival et al., 2012). The only exception to this is bacteria from the genus *Acinetobacter* which are able to colonize the skin.

Fungi and Eukarya

The most common fungal species able to colonize the skin are *Malassezia*. These lipophilic yeasts include *M. globosa* (back), *M. restricta* (scalp) and *M. sympodialis* which all reside in the sebaceous areas of the skin (Schommer and Gallo, 2013). *Pityrosporum ovalis* is another lipophilic yeast that is found on the scalp. Extremities such as the foot are often colonized by varying fungi from the genus *Aspergillus*, *Epicoccum* and *Cryptococcus* (Findley et al., 2013). Other eukaryotes in the form of arthropods also comprise the normal skin microbiota. These include mites that are found on hair follicles (*Demodex folliculorum*) and sebaceous glands (*Demodex brevis*) (Lacey et al., 2009; Clavaud et al., 2013).

Virome

There is currently limited knowledge of viruses that comprise the skin's normal microbiota. Metagenomic and genetic analyses are revealing more about the viruses that could potentially be a part of the normal microbiota, mainly human papillomaviruses; however, this is still an area of ongoing research (Foulongne et al., 2012).

Summary of skin microbiota

The skin has a residential microflora that comprises varying microorganisms. Their ability to remain in constant balance relies on the environment of the skin and host factors which can influence their survival. The microbiota composition can vary according to the host's age, hygiene and even the weather. Usually, however, microorganisms which are transient will not survive the low pH of the skin or its low moisture content.

The normal microflora of the oral cavity

The oral cavity

The oral cavity is made up of habitats whereby microbial colonization takes place. The mouth is mostly anaerobic, and bad breath—known as halitosis—is caused by the anaerobic flora of the mouth due to the excretion of sulfur compounds after protein digestion (Winkel, 2020). Oral structures such as the teeth, saliva and hard and soft palates are home to specific species within the oral microbiome (Kilian et al., 2016; Gao et al., 2018). Other structures that contribute to this heterogeneous environment include: keratinized gingiva (gums), gingival sulcus, attached gingiva, supra gingival and subgingival dental plaque (tooth biofilm above and below the gum), throat and tongue soft tissues, buccal mucosa (cheek) and lips (Kilian et al., 2016; Gao et al., 2018). Depending on which surface is colonized determines whether the microflora is more aerobic or anaerobic.

The flora of the oral microbiome was identified in the 1670s by the 'Father of Microbiology' Antonie van Leeuwenhoek. This pioneering scientist constructed his own microscopes and observed his own dental plaque samples, becoming a founder into the discovery and studies of the oral microbiome (Gao et al., 2018; Deo and Deshmukh, 2019). The oral cavity is made up of the second most diverse microbiome, comprising of over 700 species of microorganisms (Duran-Pinedo and Frias-Lopez, 2015; Gao et al., 2018; Deo and Deshmukh, 2019). Additionally, the oral cavity is the best studied microbiome as sample collection is non-invasive and easy to perform. Despite this, culturing and studying the oral microbiome has been difficult in the past due to the anaerobic environment required to imitate the anaerobic oral habitat. Currently, the ability to sequence genes and set up databases such as the Human Oral Microbiome Database (HOMD) (www.homd.org) has made studying the microbiome and oral diseases much more accessible and reliable. Dysbiosis of the oral commensal species leads to a disruption in homeostasis, which then leads to development of oral disease.

Microflora of the oral cavity

Bacteria

The predominant bacterial species in the oral microbiota may be anaerobic, facultative or obligate anaerobic. Table 1 provides insight to the many bacterial species that live symbiotically in the oral cavity (How et al., 2016). It is estimated around 500 species colonize the oral cavity, with Streptococci spp. making up around 60–90% of the bacteria that colonize teeth first after cleaning. An estimated 415 of these species are found in the subgingival plaque and supragingival plaque (Kolenbrander et al., 2002).

The Gram-negative obligate anaerobe *Porphyromonas gingivalis* (*Porphyromonas gingivalis*) is a well-known cause of gingivitis leading to chronic periodontitis—also known as gum disease and chronic inflammation of the gingiva (gums), respectively. *P. gingivalis* is a stable member of the oral microflora and able to co-habit the oral cavity, however dysbiosis leading to an increase of the bacterium causes gum disease. Good oral hygiene can prevent dysbiosis and is required to prevent biofilm formation and plaque build-up of commensal bacteria. Brushing and flossing teeth daily using dental products that contain fluoride; this controls tooth demineralization and helps to replenish calcium and phosphate ions, known as remineralization. Other bacteria present in the oral microbiome may belong to the Streptococcus or Actinomyces spp. which reside as a dental biofilm on the surface of teeth (Lemos et al., 2019). *Streptococcus salivarius* produces alkali by expressing a gene for urease when under acidic conditions and in the presence of carbohydrates (Duran-Pinedo and Frias-Lopez, 2015). The commensal bacteria may act as a barrier against pathogens, however pathogenic *Streptococcus mutans* manipulates dysbiosis due to the presence of sucrose to compete with normal microflora in the oral cavity. The first bacteria to naturally colonize teeth around 4 h after cleaning are *Streptococcus gordonii*, *Streptococcus mitis*, and *Actinomyces* spp. attach to the tooth enamel and form biofilm normally, at an almost neutral pH. At this stage, overproduction of H₂O₂ by peroxigenic bacteria may lead to the growth of pathogenic bacteria such as *S. mutans*. The take-over of biofilm by *S. mutans* modifies the biofilm microenvironment and the secretion of mutacins kills nearby competitors such as commensal streptococci (Lemos et al., 2019). The highly acidic environment leads to demineralization of the enamel, ending with dental caries. This type of cariogenesis can be prevented by practicing good oral hygiene and a limited-carbohydrate diet. However, as antimicrobial resistance is a growing concern with almost all bacterial species, *S. mutans* has been found to exhibit fluoride resistance (Liao et al., 2017).

Viruses

Viruses such as human Herpes viruses (HHV) can be found in over 70% of healthy individuals. The most common HHV commensal detected in the oral cavity is the Epstein-Barr virus (EBV) at around 60% of immunocompetent individuals (Yap et al., 2020). Invading viruses have a complex relationship with oral microflora as they can either compete with or promote one another's pathogenicity (Ma et al., 2019).

Fungal and mucosal flora

There is a high fungal oral diversity, also known as the oral mycobiome, which has only recently been discovered and studied due to the advancements of Next generation Sequencing (NGS). Recent studies have shown 75% of healthy subjects were colonized by *Candida* spp., 65% had *Cladosporium* and 50% carried *Aureobasidium* and *Saccharomycetales*. It has also been found more recently that *Malassezia* species have been found as part of the oral mycobiome, evading classical techniques, and now able to be detected due to pyrosequencing (Bandara et al., 2019). *C. albicans* is a commensal dimorphic yeast found in the oral cavity and in

Table 1 Examples of the bacterial species that make up the oral microflora.

Microbial group	Genus	Species
Gram-positive Aerobic or facultative	Streptococcus	<i>Streptococcus gordonii</i> , <i>S. mitis</i> , <i>S. auralis</i> , <i>Streptococcus salivarius</i>
	Staphylococcus	<i>S. aureus</i> , <i>Staphylococcus epidermidis</i>
	Enterococcus	<i>Enterococcus faecalis</i>
	Lactobacillus	<i>Lactobacillus casei</i> , <i>Lactobacillus fermentum</i>
	Corynebacterium	<i>Corynebacterium matruchotii</i>
Obligate anaerobic	Actinomyces	<i>Actinomyces naeslundii</i> , <i>A. israelii</i> , <i>A. viscosus</i>
	Bacillus	<i>B. cereus</i>
	Propionibacterium	<i>Propionibacterium acnes</i>
	Peptostreptococcus	<i>P. micros</i> , <i>Peptostreptococcus anaerobius</i>
	Campylobacter	<i>C. rectus</i> , <i>Campylobacter concisus</i> , <i>C. gracilis</i>
Gram-negative Aerobic or facultative	Actinobacillus	<i>A. actinomycetemcomitans</i>
Obligate anaerobic	Fusobacterium	<i>Fusobacterium nucleatum</i>
	Porphyromonas	<i>Porphyromonas gingivalis</i>
	Prevotella	<i>Prevotella melaninogenica</i> , <i>P. oralis</i> , <i>P. intermedia</i>

Adapted from How KY, Song KP and Chan KG (2016) *Porphyromonas gingivalis*: An overview of periodontopathic pathogen below the gum line. *Frontiers in Microbiology* 7: 53.

the female reproductive tract (Rossoni et al., 2018). The *Candida* spp. form biofilms on the surface of the oral cavity using yeast and hyphae of which, during dysbiosis leading to disease, cause oral pseudomembranous candidiasis—known as oral thrush. Treatment with antifungals such as clotrimazole are given for 7–14 days. Commensal *Lactobacillus* strains such as *Lactobacillus fermentum* have been shown to decrease *C. albicans* infections in healthy individuals by disrupting biofilm and hyphal formation, which further highlights the benefits of commensal flora (Rossoni et al., 2018). Other genera found in the oral mycobiota include *Penicillium*, *Aspergillus*, *Geotrichum*, *Hemispora*, *Fusarium* and more, however there is little wider literature currently to explain the roles of each within the oral mycobiome and their relation to disease.

The normal microbiota of the gastrointestinal tract

Stomach

Conditions within the stomach are highly acidic, therefore only microbes evolved to withstand these acidic conditions may survive. Consequently, the stomach typically hosts fewer commensals than other locations along the gastrointestinal tract (Ohno and Satoh-Takayama, 2020). The most influential bacterium within stomach microflora is *Helicobacter pylori* (*H. pylori*) of the Proteobacteria phyla. Proteobacteria, along with Actinobacteria, Bacteroidetes, Firmicutes, and Fusobacteria are common commensals found within gastric fluid. The colonization of commensal *H. pylori* promotes the growth of other commensal bacteria such as *Streptococcus* species (including *Streptococcus pneumoniae*, *S. thermophilus*, *S. pyogenes*, *Streptococcus parasanguinis*, *Streptococcus dysgalactiae*, *S. salivarius*, *Streptococcus suis*, *S. mutans*, and *Streptococcus agalactiae*) which maintain gut biosis (Boer et al., 2019). However, upon dysbiosis *H. pylori* may become pathogenic, reducing microflora diversity and leading to the development of stomach ulcers (Narayanan et al., 2018; von Rosenvinge et al., 2013; Jandhyala et al., 2015). Fungal *Candida* and *Phialemonium* colonies may also be found in gastric fluid. Interestingly, increased colonization of *C. albicans* within the gut has been found to exacerbate autistic behaviors. This demonstrates the influence of the microbiome on the brain (Clapp et al., 2017; Sam et al., 2017).

Duodenum

The luminal flora of the duodenum consists mainly of *Lactobacillus*, Enterococci and Bifidobacteria, with a total microbe count of 10^3 mL/luminal contents (Angelakis et al., 2015). Lactic acid bacteria produce a range of metabolites that aid the host, the most useful being Vitamin B, serotonin and (LeBlanc et al., 2013; Harper et al., 2018; Visconti et al., 2019). *Lactobacillus* populations make up 6% of total bacteria within the duodenum, however, their densities fluctuate with certain disease states. For example, colony numbers increase in cases of Rheumatoid arthritis, but decrease in cases of HIV (Heeney et al., 2018). Commensal viruses, such as the double-stranded DNA species Caudovirales, may also be found in the duodenum. Enteric viruses influence the host mucosal immune response and play an important role in the modulation of intestinal intraepithelial lymphocytes. Not only this, but they also act as indicators of disease. For example, a reduction in viral diversity is linked to irritable bowel disease (Liu et al., 2019). Moving through the intestine to the jejunum, there are high levels of *Streptococcus* and *Bacteroides* colonies. *Bacteroides thetaiotaomicron* commensals are beneficial to food digestion within the gut, for example by helping with carbohydrate metabolism. By-products from this process are then counteracted by *Lactobacillus* species; this symbiosis between commensal microbes is essential for the maintenance of healthy gut flora (Jandhyala et al., 2015). Table 2 presents the variety of bacterial flora found along the GI tract (Sekirov et al., 2010).

Table 2 Common commensal bacteria found along the GI tract.

GI Tract Location	pH	Bacteria per gram contents	Common Commensal Bacteria
Stomach	2	10^1	<i>Streptococcus</i> , <i>Lactobacillus</i> , <i>Prevotella</i> , <i>Enterococcus</i> , <i>Helicobacter pylori</i>
Small intestine	5–7	10^3 – 10^7	<i>Bacteroides</i> , <i>Clostridium</i> , <i>Streptococcus</i> , <i>Lactobacillus</i> , <i>Proteobacteria</i> , <i>Enterococcus</i>
Caecum	5.7	10^7 – 10^{11}	<i>Lachnospira</i> , <i>Roseburia</i> , <i>Butyrivibrio</i> , <i>Ruminococcus</i> , <i>Faecalibacterium</i> , <i>Fusobacteria</i>
Colon	5–5.7	10^{12}	<i>Bacteroides</i> , <i>Clostridium</i> , <i>Prevotella</i> , <i>Porphyromonas</i> , <i>Eubacterium</i> , <i>Ruminococcus</i> , <i>Streptococcus</i> , <i>Enterobacterium</i> , <i>Enterococcus</i> , <i>Lactobacillus</i> , <i>Peptostreptococcus</i> , <i>Fusobacteria</i>

Adapted from Jandhyala SM, Talukdar R, Subramanyam C, Vuyyuru H, Sasikala M and Nageshwar Reddy D (2015) Role of the normal gut microbiota. *World Journal of Gastroenterology* **21**(29): 8787–8803; Sekirov I, Russell SL, Antunes LC and Finlay BB (2010) Gut microbiota in health and disease. *Physiological Reviews* **90**(3): 859–904.

Caecum

The caecum is the location between the small and large intestines; therefore, the caecal microbiome is affected by the fluids and microbes that pass through from the upper gastrointestinal tract (Marteau et al., 2001). The bacterial density of the caecum averages at of 10^8 CFU, consisting of a variety of bacterial genera (Marteau et al., 2001; Jandhyala et al., 2015). Approximately 50% of commensal bacteria within the caecum are facultative anaerobes such as Lactobacilli and Enterococci. However, as the caecum develops into the colon, the decrease in oxygen concentrations leads to an increase in the density of anaerobic bacteria, such as *Clostridioides difficile* (*C. difficile*) (Marteau et al., 2001; Jandhyala et al., 2015). Although harmless under normal physiology, *C. difficile* can proliferate during a course of antibiotics and lead to *C. difficile* colitis (Quigley, 2013). Other potentially pathogenic commensals include *Campylobacter jejuni* and *Salmonella enterica*, of which don't become pathogenic until dysbiosis occurs. Fortunately, many beneficial commensals colonize too, including Lactobacillus and Bifidobacterium. For example, *Lactobacillus acidophilus* and *Bifidobacterium animalis* contribute to the alleviation of irritable bowel symptoms through fermentation of non-digestible prebiotics such as inulin, beta-glucans and fructo-oligosaccharides which produce short chain fatty acids (SCFAs) that help to boost the numbers of these beneficial lactic acid bacteria and bifidobacteria (Quigley, 2013; Jandhyala et al., 2015; Harper et al., 2018). Thus the presence of Bifidobacteria colonies also has been shown to improve mood in patients with chronic stress, another example of how gut microflora can affect many bodily functions (Clapp et al., 2017). Furthermore, many commensals take advantage of host tissue functions. Within the colon, commensal bacteria reside within the outer mucus layer. Every hour, crypt goblet cells secrete mucin monosaccharides to renew the inner mucus layer, of which is then converted to the outer mucus layer. The bacteria then metabolize these mucin secretions into SCFAs, harboring a continuous supply of energy (Hansson, 2012; Johansson et al., 2013).

The normal microflora of the respiratory tract

The human respiratory tract is composed of mucous membranes with two parts- the upper respiratory tract and the lower respiratory tract. The upper respiratory tract comprises the nasopharynx, oral cavity, larynx and pharynx. Microorganisms usually reside in areas where there are moist mucosal membranes and there are differences in the microbiome of each part of the respiratory tract (Unger and Bogaert, 2017). Microbes enter the upper respiratory tract during breathing and are usually trapped in the nasal passages and expelled via nasal secretions. There are some microbes however that do colonize respiratory mucosa and nasopharynx. These species include bacilli, staphylococci, streptococci, and other Gram negative species such as *Pseudomonas aeruginosa* or *Haemophilus influenzae* (Fothergill et al., 2014; Mitchell and Glanville, 2018; Watson et al., 2019). The staphylococci and streptococci residing in nasopharynx of healthy individuals remain a part of the microbiota without causing disease; likely due to the competition of nutrient resources and space from other resident microorganisms previously described. These individuals, however, are carriers of these opportunistic pathogens (Madigan et al., 2008).

The lower respiratory tract comprises the trachea, bronchi and lungs have been traditionally considered as naturally sterile sites in adults. However, recent advances in culture-independent metagenomic analyses suggest there may be commensal microbiota in healthy lung environments (Moffatt and Cookson, 2017; Carney et al., 2020; Sulaiman et al., 2020). Microorganisms and dust particles can be inhaled into the upper respiratory tract, landing on the ciliated lung epithelial cells; however, these are usually pushed up toward the upper respiratory tract where they are expelled in nasal secretions, saliva and mucus (Lanaspa et al., 2017). Few pathogens manage to reach the lungs and can cause diseases such as pneumonia. Thus, due to the inhalation process, the lungs are in contact with a range of microorganisms which have colonized the lung mucosa, some of which include the opportunistic pathogens *Pseudomonas* and *Staphylococcus* species (Blainey et al., 2012; Sommariva et al., 2020). The most common phyla include Proteobacteria, Firmicutes and Bacteroidetes of which dominant species include Prevotella, Pseudomonas, Streptococcus, Staphylococcus and Veillonella (Hilty et al., 2010; Erb-Downward et al., 2011; Beck et al., 2012; Fig. 2).

The normal microflora of the urogenital tract

The Urogenital tract in male and females comprises the urethra and bladder, and in females, the vagina. The bladder itself is another sterile site where there are no commensals. However, the urethra, downstream from the bladder, often has its own microbiota which reside on the uroepithelial cells. The gastrointestinal microflora is thought to play a significant role in urological microbiota due to the ability of bacterial population to colonize the urethra. Bacterial pathogens such as *E. coli*, *Staphylococcus saprophyticus*, *Enterococcus faecalis* and *Proteus mirabilis* are common pathogens of the urethra, often causing urinary tract infections (Ravel et al., 2011).

Fig. 2 Commensal Microbiome of the Human Body. The human body harbors microorganisms of different Kingdoms. The main phyla and species are shown above. Created using Biorender (2021).

The vagina microflora in adult females is complex. The vagina has a pH of between 3.5 and 4.5 and contains glycogen which is fermented upon by commensals of the *Lactobacillus* genus (Boskey et al., 1999). The lactic acid produced from this fermentation maintains the acidic environment, resulting in a homogenous environment for lactobacilli (such as *L. acidophilus*) to survive. Changes in this balance often result in increased risk of pathogenic infections (Fettweis et al., 2019). Yeasts such as *C. albicans* are also part of the normal vaginal microflora. Interestingly, other bacteria such as streptococci and *E. coli* can also be found in the vaginal microbiome.

Fig. 3 Physical characteristics of the Human Body. Microbial communities on the skin are based on the individuals physiological characteristics. These are dependent on whether the area is oily, moist or dry. Adapted from Byrd AL, Belkaid Y and Segre JA (2018) The human skin microbiome. *Nature Reviews Microbiology* 16(3): 143; Created using Biorender (2021).

Conclusions

The normal microflora of humans is complex and has relied on using culture based methods to determine its composition. With the wider use of metagenomic analysis, scientists are now able to examine non-culturable microorganisms in the microbiome, building up a more comprehensive picture of microorganisms from sterile and non-sterile sites in/on the human body.

Glossary

Amplicon The source or product of an amplification event, typically the product from a polymerase chain reaction.

Atopy The genetic tendency to develop allergic diseases.

Carcinogenic Having the potential to cause cancer.

Dysbiosis The imbalance between organisms found within the human microbiome.

Endodontic Relating to the soft tissues within the tooth, such as dental pulp.

Gastric Referring to the stomach.

Germ-free mice These are a subsection of gnotobiotic mice which are free of all micro-organisms.

Gnotobiotic mice Mice with only defined micro-organisms present.

Lamina propria A type of connective tissue found under the thin layer of tissues covering a mucous membrane.

Metabolome Large scale analysis of small molecules, metabolites, directly isolated from environmental or clinical samples.

Metagenomics The sequencing and analysis of genetic/genomic material extracted directly from environmental or clinical samples.

Microbiome The combined genetic material of the micro-organisms within a particular environment.

Microbiota The micro-organisms present at a particular site or habitat.

Neonates Referring to a new-born child, typically less than four weeks of age.

Operational Taxonomic Units Clustering of sequences based on similarity, typically with a similarity threshold of 97%.

Papillae Small rounded projections on part of the body.

Perinatal Covers the time a woman becomes pregnant up to one year after birth.

Periodontitis A microbial related inflammatory disease of the supporting tissues of teeth, resulting in the progressive destruction of the periodontal ligament and alveolar bone with periodontal pocket formation or gingival recession.

Virome The metagenomic sequencing of viral nucleic acids isolated directly from an environmental or clinical sample.

Introduction

Traditional classification of micro-organisms, predominantly bacteria, was borne out from the first observations of micro-organisms by Van Leeuwenhoek and focused on their corresponding morphology and physiology (Porter, 1976). From the 1960's onwards classification has alternatively centered on DNA-DNA hybridization (DDH), with both phenotypic characteristics and a high DDH value (>70%) required to class two bacteria as the same species (Stackebrandt and Goebel, 1994). The advent of high-throughput genome sequencing has allowed another method of classification based on average genome nucleotide identity (ANI). Both DNA methods of classification are used to determine taxonomy on a phylogenetic format, with organisms grouped on their evolutionary relationship. Subjectivity can arise when classifying microorganisms regarding the scientific standpoint, for example level of pathogenicity (De La Cal et al., 2012). In addition to the subjectivity used to classify micro-organisms, a further complication arises from the horizontal gene transfer between micro-organisms which cannot be easily mapped in a phylogenetic format. In 2015 an alternative method for the comparison of micro-organisms based on molecular functionality was proposed (Zhu et al., 2015). The alteration to the classification of micro-organisms over time has resulted in the re-classification of many microbial species (Burroughs and Brown, 1974; Thynne et al., 2015; Tran et al., 2017; Li et al., 2018).

Within recent years there has been increasing interest and publicity on the human microbiome both within literature and in the mainstream media, with many commercial products now marketed as supporting the health of the 'microbiome.' The human microbiome is composed of the genomes of symbiotic micro-organisms living inside and on humans including bacteria, archaea, eukaryotes (i.e. fungi and protozoans), skin mites and viruses (Balato et al., 2019), with bacteria often deemed the most predominant. These micro-organisms are located on a variety of locations within the human body with external access such as skin, gastrointestinal tract, urogenital tract, and respiratory tract. Furthermore, these micro-organisms are known to provide traits which humans did not evolve on their own (Gill et al., 2006).

Cell for cell, bacteria have long been described as significantly outnumbering human cells with a ratio of 10: 1 often quoted from the work by Thomas Luckey in 1972 (Luckey, 1972). This statement has however been brought into question and in 2016 Sender et al. reviewed a wide range of experimental data and estimated that within a 70 kg reference man there would be 3.8×10^{13} bacterial cells, corresponding to a mere 0.2 kg, with a comparable order of human cells at 3.0×10^{13} (Sender et al., 2016). This suggests that the actual ratio of bacterial to human cells is far closer to a 1:1 ratio. With bacteria only one component within the human microbiome, it is possible that when taken in its entirety (including fungi, archaea, protozoa and viruses) in terms of absolute numbers the total microbiome would indeed be far greater than cells of human origin.

Determination of diversity within the human microbiome

Traditionally, studying the microbiome has been reliant on the presence of cultivable microbes using techniques such as culture, PCR, or gel-based methods. Advances in culture-independent techniques and metagenomic sequencing analysis have aided the breadth of micro-organisms identified. Despite these advances there continues to be a dearth of information regarding non-bacterial species (Andersen et al., 2013; Amato et al., 2019) as well as a bias for known bacterial species (Jenkins et al., 2018; Watson et al., 2019). The following section discusses the methodologies used to determine microbial diversity and the corresponding advantages and disadvantages of each (Table 1), as well as the importance in study design and models for human microbiome research.

Methodologies

Historically, the identification of bacterial taxa related to the human microbiome would have involved culture-based methodologies (Rodríguez-Valera, 2002; Schleifer, 2004). This could involve differential growth on selective media (carbon source utilization) or growth under selective conditions (presence of antibiotics). Despite widespread use across literature there are many drawbacks to this approach. The key problem is that the majority of bacteria are deemed 'unculturable' (Stewart, 2012) and these methods for example can only identify around 50% of the estimated 700 bacterial species within the oral microbiome (Zhao et al., 2017). This problem is exacerbated by the use of selective medias which can bias towards the growth of particular strains (Gorski, 2012). This can result in the exclusion of slow-growing species and preference species which would ordinarily be at low abundance within the sample.

Over the years, researchers have moved towards more DNA-based methods for determining microbial diversity within the microbiome. This has included the use of gel-based techniques, PCR methods, DNA micro-arrays and nucleotide sequencing (Deo and Deshmukh, 2019). Gel-based methods include Denaturing Gradient Gel Electrophoresis (DGGE) and Temperature Gradient Gel Electrophoresis (TGGE), which are inexpensive methods, sensitive to one base pair difference and can be performed rapidly (Miller et al., 1999; Liu et al., 2006). Polymerase Chain Reaction (PCR) methods include Restriction Fragment Length Polymorphisms (RFLP), Real-Time PCR, and Random Amplified Polymorphic DNA (RAPD) (Nocker et al., 2007). These methods typically show high sensitivity and are fast but can introduce PCR bias potentially missing the species at lower abundance (Gonzalez et al., 2012). Phylogenetic DNA micro-arrays can prove valuable for high-throughput, systematic, quantitative analysis of bacterial communities within different microbial ecosystems (Parolin et al., 2017).

Table 1 The advantages and disadvantages for different methods for studying the microbiome (Everett et al., 2010; Green et al., 2015; Escobar-Zepeda et al., 2015; Environmental Chemicals, the Human Microbiome, and Health Risk: A Research Strategy, 2018).

<i>Method</i>	<i>Advantages</i>	<i>Disadvantages</i>
<i>Culture- based methods</i>	<i>Selective for viable micro-organisms</i>	<i>Bias for easily cultured micro-organisms</i>
<i>DNA-based methods</i>	<i>High sensitivity and reproducible</i>	<i>Bias towards most abundant species</i>
TGGE/DGGE analysis		
DNA microarrays	Reproducible, high sensitivity and rapid	PCR bias Co-migration of DNA molecules
Nucleotide sequencing:	High capacity Offers phylogenetic analysis of microbial populations	Complexity in design and time required for analysis Offers no differentiation between viable and non-viable micro-organisms
Amplicon sequencing	High sensitivity Identification from mixed samples (containing human and other non-microbial contamination) Readily used and reasonably inexpensive	Only generates genus level phylogenetic profiles High reliance on method for nucleotide extraction Only really used for bacterial analysis and to a much lesser extent Eukaryotic microbes
Metagenomics	Resolves species and strain level phylogenetic profiles Provides genome content and functional potential based on metabolic gene analysis	Expensive technique Lower tolerance of non-microbial contaminants within samples Requires complex and computationally expensive analytic approach
Culture-independent molecular profiling	Allows identification of molecules/proteins key to micro-organism to micro-organism or micro-organism to host signalling	Samples specifically prepared for relevant target molecules, preventing analysis of multiple molecules simultaneously Potentially poor differentiation of human or microbial derived molecules
Metabolomic		Sensitivity varies dependent on precise method used
Metaproteomic	Can identify key secreted and intracellular microbial products Can improve understanding of relevant proteins and post-translational modifications accordingly	
Direct Observations	Provides detailed spatially relevant information regarding host-microbe interaction Can provide in situ information	Technically challenging to conduct and verify Less depth in taxonomic results
Electron microscopy	TEM/SEM allow direct visualization of microbial community within fixed sample	No identification of microbial taxa or traits
FISH	Evaluates taxonomy, location, and organization of microbial communities within fixed sample Offers insight into spatial distribution of bacteria Allows quantification and sorting of microbes from microbiome sample (following dissociation of microbial community	Lower resolution, particularly in host tissues with high levels of opacity
FACS		

More recent studies have utilized nucleotide sequencing to characterize microbial populations within the human microbiome (Willing et al., 2010; Brubaker and Wolfe, 2015; DiGiulio et al., 2015). This can be broadly split into amplicon sequencing and metagenomics, with both methods utilizing either Sanger sequencing (Franc et al., 2002) or next generation sequencing (Goodwin et al., 2016). Amplicon sequencing is a method which utilizes the amplification of a specific gene which is deemed unique to the micro-organism, typically at the genus level (Escobar-Zepeda et al., 2015). Typically ribosomal ribonucleic acids (rRNA) genes are utilized for amplicon sequencing, 16S rRNA for bacteria and 18S rRNA for eukaryotes, although the internal transcribed spacer (ITS) is also used for eukaryotic microbes (Hamady and Knight, 2009; Findley et al., 2013). Amplicon sequencing is one of the most prevalent methods used in microbiome research, however some caution is required with this approach as *Escherichia* spp. and *Shigella* spp. were found to have identical sequence along all of the 16S ribosomal RNA (rRNA) genes (Zuo et al., 2013). Furthermore, nucleotide extraction is of key importance for full utilization of this method, with some techniques destroying subsets of micro-organisms (Gohl et al., 2016; Environmental Chemicals, the Human Microbiome, and Health Risk: A Research Strategy, 2018). Advances in next generation sequencing have led to a rise in the use of whole-genome shotgun sequencing/metagenomics in studying the human microbiome (Venter et al., 1998). This method involves the random shearing of DNA by a shotgun method and can result in the complete profiling of gene content within the sample (Venter et al., 1998). Providing information on metabolic pathways and functional profiles of the microbial communities, as well as removing bias that can be observed with amplicon sequencing. This methodology has yet to fully replace amplicon sequencing due to the associated costs and the increased complexity in detailed analysis of results (Environmental Chemicals, the Human Microbiome, and Health Risk: A Research Strategy, 2018).

Both amplicon sequencing and metagenomics produce valuable information regarding the microbial composition and diversity within a sample, however they do not differentiate between viable and non-viable cells.

Methods to study viable microbial communities within the human microbiome include direct observation methods such as electron microscopy (Croucher et al., 1983), fluorescent *in situ* hybridization (FISH) (Franks et al., 1998), and cytometric microbiome profiling (utilizing flow cytometry and sequencing) (Vandeputte et al., 2017). These analyze the microbiome *in situ* and offer insights into spatial distribution, however this can be limited by the behavior of microbes within their environment and the opacity of the host tissue (Wiles et al., 2006). Viability tests including growth studies (based on optical density), colony structure or direct enzymatic screens, can be used to support *in situ* analysis however these can bias towards easily cultured micro-organisms (Environmental Chemicals, the Human Microbiome, and Health Risk: A Research Strategy, 2018).

Culture-independent molecular profiling using metabolomics or meta-proteomics, via nuclear magnetic resonance (NMR) or mass spectrometry techniques, provides information on host: micro-organism or micro-organism: micro-organism interactions (Zhang et al., 2019). Varying sensitivity levels and the specific requirements for monitoring target molecules, however, prevents simultaneous analysis from single sample collection (Environmental Chemicals, the Human Microbiome, and Health Risk: A Research Strategy, 2018).

Sampling

The type and methods of sample collection for studying the human microbiome can have a substantial impact on the quantity and quality of data obtained. Sampling methods differ depending on the body site of interest and range from swabbing the area of interest to collection of stool samples (Aagaard et al., 2013). Different sampling methods for the same area can result in alterations in observed microbial composition. The plethora of micro-environments within the oral cavity has resulted in a variation in findings between individual studies dependent on sampling methods, for example site-specific sampling (sub-lingual plaque) (Aas et al., 2007) versus global sampling (oral rinses) (Ghannoum et al., 2010). Another consideration with regards to sampling is the methods of storage prior to analysis. Temperature, length of storage, and hypoxic conditions all contribute to the observed microbial composition (Jenkins et al., 2018), with repeated freeze-thaw cycles also shown to alter the microbial composition (Sergeant et al., 2012).

Study design

A large proportion of microbiome studies utilize animal models, particularly rodents, as they are effective models and their environment can be tightly controlled. The way the animals are born and raised has a large impact on the microbiome studies, with the maternal effect (inoculation of rodents at birth) as well as individual diet and co-habitants factoring into the diversity and composition of the microbiome (Ley et al., 2005; Rawls et al., 2006). The use of germ-free mice can circumvent the maternal effect by allowing the introduction of identical pre-determined inoculum to mice of different genetic make-up. Environmental factors can also alter the results of microbiome studies, with mice obtained from different vendors found to contain varying levels of segmented filamentous bacteria within their gut microbiome (Ivanov et al., 2009).

Alternatively, human samples can be used in microbiome studies with the main advantage that these studies directly relate to the human microbiome. Controlling the environment is far harder in these studies as there are many factors which can influence the microbiome including age, pregnancy, diet, and the use of antibiotics (Goodrich et al., 2014). Correspondingly, many will involve the use of exclusion criteria when recruiting individuals. Further problems can involve the identification of effective controls, although temporal studies can establish a control by utilizing an initial baseline for the individual. Comparison of human microbiome studies would be greatly enhanced by the introduction of standardization of protocols and study design, with recent literature suggesting ways of achieving this (Goodrich et al., 2014; Poussin et al., 2018; Greathouse et al., 2019).

The Human Microbiome Project

In 2008 the NIH Common Fund Human Microbiome Project (HMP) was established, with the aim of creating resources to allow the comprehensive understanding of the human microbiome and its role in health and disease. This project has resulted in the sequencing of >2200 reference strains isolated from five body sites (Table 2) of 300 healthy adults between 18–40 years old and a plethora of publications (Gevers et al., 2012; Huttenhower et al., 2012; Ward et al., 2012; Proctor et al., 2019). It is a consortium which studies many clinically relevant body-sites with paired 16S profiling and deep metagenomic sequencing coverage using a large cohort of participants to accommodate for the high intra- and inter-personal variation observed within the human microbiome (Gevers et al., 2012). As multiple sequencing centers were used over a prolonged duration for the HMP, effort was taken to standardize and benchmark protocols for sample collection (Huttenhower et al., 2012), handling and 16S profiling (Ward et al., 2012).

Table 2 Specimens taken from the five major body sites for the Human Microbiome Project, with 18 samples taken for women and 15 for men (minus three vaginal samples) (Huttenhower et al., 2012).

Body site	Specimens taken
Oral Cavity and Oropharynx	Saliva
	Buccal mucosa (cheek)
	Keratinized gingiva (gums)
	Palate
	Tonsils
	Throat and tongue soft tissue
	Supra and Subgingival dental plaque (tooth biofilm above and below the gum)
Nasal cavity	Anterior nares (nostrils)
Skin	Retro auricular creases (behind each ear)
	Antecubital fossae (inner elbows)
Gastrointestinal tract	Self-collected stool sample
Urogenital tract	Vaginal introitus
	Vaginal midpoint
	Posterior fornix

Diversity across the microbiome

Microbial diversity across body sites

The majority of microbiome studies, including the Human Microbiome Project, have focused on five major body sites (Table 2). The level of diversity observed across different body sites is variable, with variation observed at an inter-personal level (between subjects), intra-personal level (between body sites of the same subject) as well as temporally (within a single body site) (Costello et al., 2009; Grice et al., 2009; Turnbaugh et al., 2009a). In this section what is known about the diversity in specific body sites and how these are known to be affected between individuals is discussed.

Oral cavity

In 2019 the oral cavity was described as second only to stool samples regarding microbial richness determined by operational taxonomic units (Deo and Deshmukh, 2019). The oral cavity and associated nasopharyngeal areas are well suited to microbial growth due to consistent temperature, neutral pH (6.5–7) and high levels of hydration (Lim et al., 2017). In addition, it is a complex body site because of the number of individual microenvironments located within it including the subgingival dental plaque, supragingival dental plaque, keratinized gingiva (gums), palate, buccal mucosa (cheek), tonsils and throat (Gao et al., 2018). Research into the oral microbiome is supported by both the human oral microbiome database (Chen et al., 2010), which contains approximately 700 culturable prokaryotic species analyzed by 16S rRNA sequencing, and the Human Microbiome Project (Huttenhower et al., 2012).

The micro-environments found within the oral cavity provide niche environments for different types of bacteria, with microbial diversity linked to the micro-environments. High microbial diversity was observed on the tongue linked to numerous papillae with few anaerobic sites, whereas conversely the buccal and palatal mucosae were found to be low in microbial diversity (Sultan et al., 2018). Despite the association between microbial diversity and specific oral micro-environments, *Streptococcus* spp. were still shown to dominate at most micro-environments (Chen et al., 2010; Huttenhower et al., 2012). Composition of bacterial communities does however vary between the oral micro-environments showing higher prevalence of genera at individual sites, with a higher abundance of *Hemophilus* spp. at the Buccal mucosa, *Actinomyces* spp. at supragingival plaque and *Prevotella* spp. at the subgingival plaque (Huttenhower et al., 2012; Gao et al., 2018).

High inter-personal variation within the oral microbiome relating to carriage of taxa, species and strain level has been noted, despite observed conservation across metabolic pathways within a healthy population (Ahn et al., 2011). One study also found the conservation of fifteen bacterial genera within the healthy oral microbiome across ten different individuals including conservation of the following species: *Streptococcus oralis*, *Hemophilus parainfluenzae*, *Actinomyces odontolyticus*, *Prevotella melaninogenica* and *Campylobacter gingivalis* (Bik et al., 2010).

Studies into the difference between the oral microbiome and pathogens of modern populations versus ancient population, suggest that microbial diversity is comparatively decreased in modern populations with the suggestion that this could relate to the chronic oral disease observed in post-industrial lifestyles (Ursell et al., 2012; Adler et al., 2013; Metcalf et al., 2014). This observation is in part put down to alterations to diet and a further study into the mobile genetic elements from oral samples of North Americans compared to Fijians showed high variation (Brito et al., 2016) suggesting diet and environmental factors are key.

One study into the oral fungal microbiome found 74 culturable and 11 unculturable fungal genera (Ghannoum et al., 2010). *Candida* spp. were the most dominant, present in 75% of samples, with other prevalent genera including *Cladosporium*,

Aureobasidium, *Saccharomycetales*, *Aspergillus*, *Fusarium* and *Cryptococcus* (Ghannoum et al., 2010). These findings share some overlap with previous studies on the oral fungal microbiome (Salonen et al., 2000; Jabra-Rizk et al., 2001), with differences likely relating to alternative sequencing techniques or sample size. The identification of environmentally sourced fungal species within the oral microbiome is hypothesized to link to inhalation/consumption of spores from the environment (Ghannoum et al., 2010). Just as bacterial commensals within the oral cavity can offer protection against pathogenic bacteria, it is thought that a similar protective effect could be observed with fungal species.

Skin

The greatest level of bacterial diversity is observed within the skin microbiome, in particular at the palms, fingers and forearms with these sites showing higher levels of diversity than those observed within the gut or oral cavity (Costello et al., 2009), although more recent studies have brought this into question (Deo and Deshmukh, 2019). One of the reasons for the high bacterial diversity is that the skin microbiome is consistently altered by both lifestyle and environmental factors (Ursell et al., 2012; Prescott et al., 2017). There are still, however, predominant bacterial species observed, with >90% of the microbiota on the forearm composed of Actinobacteria, Proteobacteria and Firmicutes (Gao et al., 2007). Regardless of this there is very high inter-personal variation, with only 2% of species level operational taxonomic units (OTUs) for the volar forearms shared between individuals (Gao et al., 2007). Furthermore, within the same individual there is only 28% (13.5 out of 48) of species-level OTUs shared between the left and right forearms (Gao et al., 2007), and only 17% between hands of the same individual (Fierer et al., 2008).

One study into the fungal microbiota within the skin, showed that majority of sequences obtained from the forearm resembled *Malassezia* (Paulino et al., 2006). This study was not extensive however due to the low level of 18S rDNA sequences present within GenBank at time of publication. Future advances in sequencing techniques could allow for the better determination of the true breadth of fungal species observed within the natural microbiome.

Gastrointestinal tract

The gastrointestinal tract (GI tract) encompasses microbiota for the mouth (although oral cavity will be treated as a separate body site here), stomach, duodenum, colon, and fecal samples. Due to ease and non-invasive nature of sampling, the majority of studies look at fecal samples when establishing microbiome data (Arumugam et al., 2011; Le Chatelier et al., 2013; Ren et al., 2019).

Studies looking into the observed diversity across the gastrointestinal tract, showed highest diversity within the oral cavity and lowest diversity within the stomach but importantly demonstrated an observable gradient of increasing diversity moving from the stomach, to the duodenum, to the colon through to the fecal samples (Stearns et al., 2011). With greatest clustering of bacterial species between variant sites rather than between individuals or across sexes (Stearns et al., 2011). Further research has supported the idea of a gradient across the GI tract with Enterobacteriaceae observed with greater frequency towards the distal end of the GI tract and *Streptococcus* spp., *Enterococcus* spp., and *Corynebacterium* spp. showing greater abundance at the proximal end of the GI tract (De Cárcer et al., 2011). Gut microbiota have been classed as one of three enterotypes based on the dominance of either *Bacteroidetes*, *Prevotella* or *Ruminococcus* however these enterotypes are better described as microbial gradients rather than discrete communities (Arumugam et al., 2011).

The prevalence of these bacterial groups within the gut microbiome has been shown to be heavily dependent on diet, with *Bacteroidetes* commonly associated with long-term diets high in protein and animal fat and *Prevotella* conversely associated with long-term diets high in carbohydrates (Wu et al., 2011). It has been suggested that the gut microbiota has co-evolved with mammals to suit their respective diets resulting in more specialized communities for herbivores, carnivores or omnivores (Ley et al., 2008; Muegge et al., 2011). Both studies using mono/dizygotic twins and gnotobiotic mice have been used to study the impact of diet on a genetically similar background. The GI tract microbiome has been linked to the weight of individuals, with obese individuals shown to have lower diversity compared to those of lean weight (Turnbaugh et al., 2009a). This has been further typified by the ratio of *Bacteroidetes*: *Firmicutes* within the gut microbiota, with *Bacteroidetes* levels increasing within the ratio in people consuming fat-restricted or carbohydrate-restricted diets for one year (Ley et al., 2006). A study looking at this within gnotobiotic mice found that mice colonized by obese microbiota could have their microbiome rescued by the invasion of a particular *Bacteroidetes* species from lean microbiota when co-housed (Ridaura et al., 2013). It is important to note, however, that the observed effect resulting from fecal transplant was completely overridden by diet of the mice.

With diet such a key determinant in the diversity in the GI Tract it is of little surprise that the diversity of the gut microbiota varies greatly during the first two years of a human's life. Several studies across the USA and Europe have explored the impact of breastfeeding versus bottle feeding on the baby gut microbiome (Penders et al., 2006; Fallani et al., 2010; Levin et al., 2016; Ho et al., 2018). Human breast milk is known to contain immunoglobulins, fatty acids, hormones and cytokines (Ballard and Morrow, 2013) and in more recent years has been shown to be both prebiotic and probiotic in nature (Moossavi et al., 2018). Consequently, it is now believed that breastmilk can both directly and indirectly impact the gut microbiome of the nursed infant. The microbiota of breastmilk has been shown to have high levels of inter-personal variation with common bacteria including *Streptococcus* spp., *Staphylococcus* spp., *Propionibacteria* spp., lactic acid bacteria and *Bifidobacterium* spp. (Collado et al., 2009; Hunt et al., 2011; Fernández et al., 2013). Studies comparing breastfeeding against formula feeding have consistently shown lower bacterial diversity within breastfed infant's gut microbiota (Bäckhed et al., 2015; Thompson et al., 2015; Rautava, 2016). It is also apparent that breastfeeding is a large predictor of infant gut microbiota (Kim et al., 2019).

Recent data has also suggested a possible link between diversity within the gut microbiome and personality traits (Christian et al., 2015; Kim et al., 2018; Johnson, 2020). Greater microbial diversity within the gut microbiome has been observed in extraverted

individuals both as children (Christian et al., 2015) and adults (Johnson, 2020) compared to introverted individuals. Increased sociability has been linked to an abundance of *Akkermansia*, *Lactococcus* and *Oscillospira* species, and neurotic tendencies (anxiety and stress) have been described as a negative predictor for the abundance of *Corynebacterium* and *Streptococcus* species (Johnson, 2020).

Urogenital tract

The majority of research into the urogenital tract microbiome has been focused on women of reproductive age, predominantly due to the increased burden of urogenital diseases within women (~81% of urinary tract infections occur in women) (Salvatore et al., 2011; MacIntyre et al., 2017). Urogenital tract microbiome research covers three key areas, the lower reproductive tract (vagina and cervix), the upper reproductive tract (uterus) (Moreno and Simon, 2019), and the urinary tract (Burton et al., 2015).

The lower reproductive tract has low microbial diversity and is typically dominated by *Lactobacillus* spp. (Huttenhower et al., 2012). The microbiome of the lower reproductive tract have been classified as one of five identified groups (named community state types (CST) I-V) (Ravel et al., 2011). CST groups I, II, III and V contain high abundances of particular *Lactobacillus* species, with CST I dominated by *L. crispatus*, CST II dominated by *L. gasseri*, CST III dominated by *L. iners* and CST V dominated by *L. jensenii*. The CST group IV however contains low levels of *Lactobacillus* spp. and instead demonstrates a high diversity of facultative/strict anaerobes including, *Prevotella*, *Gardnerella*, *Megasphaera*, *Sneathia*, *Atopobium* species.

The upper reproductive tract was originally thought to be sterile (Ansbacher et al., 1967) but more recent research has implied the presence of a uterine microbiome (MacIntyre et al., 2017). Overall, the uterine microbiome is thought to share certain similarities to that of the lower reproductive tract, however around one fifth of individuals sampled (6 out of 26) showed a marked difference between the two sites (Moreno et al., 2016). The majority of uterine microbiomes can be divided into three classifications: low diversity, *Lactobacillus* spp. dominated profiles or high diversity (MacIntyre et al., 2017).

The urinary tract was also originally thought to be sterile due to the hostile environment created by urine, which is a hypertonic solution of low pH containing high concentrations of urea and other antibacterial compounds, coupled with the regular mechanical voiding and filling (Ipe et al., 2016; Tang, 2017). Microbes that can therefore thrive within the urinary tract require mechanisms to protect them from or negate the harsh conditions. Bacteria associated with the urinary tract microbiome include *Lactobacillus*, *Staphylococcus* and *Gardnerella* species (Wolfe et al., 2012; Pearce et al., 2014; Brubaker and Wolfe, 2015). There are, however, limitations to detecting microbial composition within urine dependent on the sampling method. More recent studies looking at suprapubic aspiration (Wolfe et al., 2012) or transurethral catheterization samples (Hilt et al., 2014; Karstens et al., 2016; Thomas-White et al., 2016) are detecting more complex microbial communities which differ from those seen in either the vagina or gut. As with many other body site microbiomes there is a high degree of inter-personal variation (MacIntyre et al., 2017). The urinary tract microbiome is still believed to be of a lower abundance and less diverse than other body sites (Pearce et al., 2014).

Sex-dependent microbial variation

The diversity and composition of several human microbiota (skin, gut and urogenital) vary between males and females, these differences have been linked to the anatomical and hormonal differences between the two sexes.

Differences between the sexes has been noted within the skin microbiomes (Sanmiguel and Grice, 2015; Ying et al., 2015). One study looking into the similarities of skin microbiomes between sexually active cohabiting couples also identified various micro-organisms which were disproportionately abundant on each biological sex (Ross et al., 2017). Diversity in female skin microbial communities was significantly higher than the male counterparts. Interestingly, the differences between the sexes was so significant for the skin microbial communities on the thighs that they were able to correctly classify the sex from which the sample originated with 100% accuracy (Ross et al., 2017). Microbial communities on the thighs in females contained significantly more Proteobacteria and 11-fold more *Lactobacillus* spp. (commonly found within the vaginal microbiome), whilst males showed a greater abundance of Actinobacteria.

The composition of bacterial species observed within the gut microbiota are significantly different between the sexes. In one study males were seen to cluster together and were enriched for *Faecalibacterium prausnitzii*, *Bifidobacterium* spp., *Bacteroidetes* spp., *Clostridium* spp., *Enterococcus* spp., and *Prevotella* spp. (De Cárcer et al., 2011). Conversely, females showed enrichment of *Streptococcus* spp., *Veillonella* spp., *Mannheimia* spp., and *Ruminococcus* species. With diet deemed the major determinant of the gut microbiome (Conlon and Bird, 2014) these observed differences could have multiple interpretations, from the implication of a basal difference between sexes to highlighting the potential variation between the diets of males compared to females.

With arguably one of the greatest differences in anatomy between the two sexes, it is unsurprising that there are differences in microbial composition of the urinary tract. Regardless, both sexes contain *Lactobacillus* spp., *Streptococcus* spp. and *Corynebacterium* species (Fouts et al., 2012; Nelson et al., 2012; Lewis et al., 2013). Within women of child-bearing age *Lactobacillus* spp. are predominant within the urinary tract microbiome, conversely within men a higher abundance of *Corynebacterium* are observed (Fouts et al., 2012). Differences between the microbial compositions of men and women is also related to the changes in urine composition between the sexes, with women having more citrate and less calcium and oxalate and men containing an increased amount of creatinine (Ipe et al., 2016).

Environmental factors and microbial diversity

The role of the environment in altering the human microbiome has been reviewed (Laursen et al., 2015; Ross et al., 2017), particularly the effect of co-habiting with other humans or pets. The microbial taxa observed within skin, oral and gut microbiomes of co-habiting families have been shown to resemble each other (Song et al., 2013). In 2017 Ross et al. showed that partners of sexually active cohabiting couples could be predicted 86% of the time based on their skin microbiome profiles, with greatest similarity in microbial skin population observed across their feet (Ross et al., 2017). In addition to these observations between co-habiting humans, similar observations have been noted for pet owners. Indoor pets, such as dogs, are known to alter the microbial content within the vacuumed house dust and on surfaces within the household (Sitarik et al., 2018). Research into how pets alter the composition of the gut microbiome in infants, demonstrated an altered gut microbial composition in neonates at one month with an increased abundance of an animal derived *Bifidobacterium pseudolongum* strain (Nermes et al., 2015). There have been other studies investigating the effects on infants at different ages of three, four, nine, and eighteen months which have found enrichment and depletion of various bacterial genera (Azad et al., 2013; Laursen et al., 2015; Tun et al., 2017). Overall, the research suggests that although pets were not associated with overall gut bacterial diversity/richness, they did determine variations in the observed abundance of specific genera. Various studies have looked into the reduction in the development of atopy in children exposed to pets at a young age, the majority of research has generated mixed results with only protection against the development of allergy to the type of pet exposed consistently noted (Wegienka et al., 2010; Kim et al., 2019).

Geography and ethnicity observed microbial diversity

With lifestyle and environmental factors shown to impact the composition and diversity observed within the microbiome (Conlon and Bird, 2014; David et al., 2014; Laursen et al., 2015; Ross et al., 2017), it is perhaps logical that geography also impacts variation within microbiomes. One study using twins from South Korea and the USA showed that there was great variation within the composition of the gut microbiome despite similarities at the OTU level (Lee et al., 2011). Most gut microbiome studies have focused on what is commonly described as western populations, including individuals from Europe, the USA and Canada. With diet such a key aspect to determining the composition of the gut microbiome (David et al., 2014; Hullar and Fu, 2014), this has been seen as a limitation within gut microbiome studies, given the expected similarity between many westernized diets. One study comparing the gut microbiome of children from Europe to those from Burkina Faso, showed the latter had an increased level of Bacteroidetes and reduced levels of Firmicutes when compared to those from Europe (De Filippo et al., 2010). Another study looking at the Japanese gut microbiome found increased prevalence of *Bacteroides plebius*, a species which encodes the enzyme porphyranase which is known to naturally degrade seaweed (Hehemann et al., 2010). This study is interesting as it highlights how cultural diets can have an impact on microbiome communalities within a geographical area. This is equally seen for the Hazda hunter-gatherers which have a seemingly unique gut microbiome composition, presumed to be linked to their foraging lifestyle. These studies highlight the importance of geography, and potentially key dietary differences, when establishing a baseline for a healthy gut microbiome. Bacterial diversity within the oral cavity, unlike that within the gut, demonstrates no clear geographical patterns with greater variation seen between individuals of the same location than those between different locations (Nasidze et al., 2009). Variations in composition of microbial communities have however been observed between different geographical areas. An example of this is the identification of Enterobacteriaceae in 28% samples taken from the Congo, whereas members of this taxa was not observed in any samples from China, Germany, Poland, Turkey or California (Nasidze et al., 2009).

The impact of ethnicity on microbiota is complex, with a multifactorial approach required to establish true associations (Fortenberry, 2013). One study looked at the variation within the vaginal microbiome of women of different ethnicities and found a greater dominance of lactic acid producing *Lactobacilli* in women of Caucasian and Asian ethnicities compared to those of African American or Hispanic ethnicities (Zhou et al., 2007; Ravel et al., 2011). The observed variation was proposed to link to the lower pH levels observed in Caucasians and Asian women compared to the other ethnicities studied.

Temporal variation in microbial diversity

Alterations to the bacterial diversity within the human microbiome over time have been noted for various body sites (Dekaboruah et al., 2020). The top three body sites showing temporal variation include the skin, the gut and the oral cavity (Caporaso et al., 2011).

The gut microbiome is perhaps one of the more interesting and classical examples of temporal variation within microbial diversity. The guts of new-born babies are rapidly colonized by their mother's microflora (either from the vagina or skin depending on delivery method) which is then followed by a linear increase in diversity to 2 years old at which point it resembles a healthy adult (Koenig et al., 2011). One reason for the observed temporal change in gut microbiome at this stage is the prominent alteration in diet within the first two years of life. Interestingly, microbial diversity in the oral cavity will continue to evolve from childhood all the way to the age of eighteen when it will represent an adult oral microbiome (Crielaard et al., 2011).

There are four key components to understanding temporal change: constitutive differences observed between subjects, time-varying dynamics over several months, biological noise (background variations between time points), and technical noise (variation between replicates at a single time point) (Lloyd-Price et al., 2017). Assessing temporal changes using these four components allows the determination of genuine variations in diversity from background noise. Using this methodology, a paper in 2017 on the expanded Human Microbiome Project found that the gut microbiome composition altered in a temporal

fashion (Lloyd-Price et al., 2017). Within adults Firmicutes demonstrated greatest variation by temporal dynamics within an individual whereas conversely Bacteroidetes primarily showed inter-individual variation.

Temporal changes can also be observed within the urogenital tract with the composition and diversity of the lower reproductive tract in women shown to change throughout their reproductive lifecycle. Following microbial seeding of the site during birth (Dominguez-Bello et al., 2010), a surge in maternal estrogen results in the thickening of epithelium and production of glycogen (a key carbon source) which supports growth of lactic acid producing bacteria (Cruickshank and Sharman, 1934; Spear et al., 2014). As the levels of maternal estrogen drop there is then an increase in bacterial diversity and consequently pH, as the abundance of lactic acid producing bacteria drops (Hammerschlag et al., 1978a, b; Farage and Maibach, 2006). During pregnancy, levels of the hormone estrogen increase substantially and the microbial diversity within the vagina is known to reduce with an increase in dominance of *Lactobacillus* spp. (MacIntyre et al., 2015). Post-birth the estrogen levels reduce by around 1000-fold (Nott et al., 1976) and this results in a reduction of *Lactobacillus* spp. and increase in bacterial diversity persisting for one year (DiGiulio et al., 2015). Post-menopause the composition is shown to alter again with estrogen levels reducing alongside a thinning of the epithelium and glycogen levels, resulting in vaginal atrophy and dryness and correspondingly a depletion of *Lactobacillus* spp. and increase in bacterial diversity (Brotman et al., 2018). There is a strong connection between hormone levels and microbial diversity observed within the lower reproductive tract and women who receive hormone replacement therapy continue to have *Lactobacillus* dominated microbiomes (Muhleisen and Herbst-Kralovetz, 2016). Within the urinary tract the microbiome has also been noted to change between children and adults (Tang, 2017). In part this is related to the alterations observed in diet, personal hygiene, and voiding habits. This alteration continues throughout life with abundance of *Lactobacillus* spp. notably increased during puberty and decreased in post-menopausal women (Burton et al., 2015; Karstens et al., 2016; Thomas-White et al., 2016).

Dysbiosis within microbiota and disease

The dysregulation of parts of the human microbiome have long been hypothesized to link to various disease states either directly by reduction in competition for pathogenic species (Blaser and Falkow, 2009) or indirectly by activating the immune response (Kau et al., 2011). The last decade has seen an abundance of research on the potential links between alterations in the diversity of the human microbiome and related diseases (Cho and Blaser, 2012; Karlsson et al., 2013a; Wade, 2013; Scher et al., 2015).

Obesity

According to the World Health Organization (WHO) the prevalence of obesity, individuals with a body mass index (BMI) ≥ 30 , has drastically risen over the last five decades with >650 million adults worldwide classed as obese in 2016. Obesity is listed as a major risk factor in the development of cardiovascular disease (Van Gaal et al., 2006), diabetes (Lazar, 2005), musculoskeletal disorders (Wearing et al., 2006), certain cancers (Wolin et al., 2010) and poor outcomes from infectious diseases such as SARS-CoV-2 (Simonnet et al., 2020). Multiple studies have investigated the role of the gut microbiota in altering and determining obesity (Turnbaugh et al., 2009a; Schwiertz et al., 2010; Ravussin et al., 2012; Ridaura et al., 2013). Firmicutes and Bacteroidetes are commonly found within the healthy gut microbiome (Ley et al., 2006; Lagier et al., 2012). The ratio of Bacteroidetes to Firmicutes has been linked to the bodyweight of mice, with a lower ratio observed in obese mice compared to their lean counterparts (Ley et al., 2005; Turnbaugh et al., 2006). The alterations within this ratio has however been contradicted by other studies (Schwiertz et al., 2010), most probably due to alterations in methodologies, sample size and study design. A study within twins showed obesity was associated with a decreased abundance of Bacteroidetes species coupled with overall reduced bacterial diversity (Turnbaugh et al., 2009a). This study also highlighted an enrichment of genes related to lipid and carbohydrate metabolism in obese individuals. Gastric by-pass surgery within obese individuals was shown to alter specific metabolic markers such as the production of urinary amines and cresols (Li et al., 2011). Interestingly, transplantation of obese microbiota to germ-free mice resulted in an obese phenotype (Turnbaugh et al., 2006). This observation has been supported by a study using human donors, whereby the introduction of fecal transplants resulted in the host phenotype (Turnbaugh et al., 2009b), so suggesting a direct correlation between the microbiome and the obese phenotype. The observed correlation is however overridden by diet (Turnbaugh et al., 2009b; Ravussin et al., 2012). A further study showed perinatal administration of *Lactobacillus rhamnosus* decreased excessive weight gain during childhood (Luoto et al., 2010). Collectively these studies suggest that there is a modifiable factor regarding the gut microbiome which can alter the level of obesity within individuals.

Diabetes

Diabetes is a chronic, metabolic disease which is characterized by the elevated levels of blood glucose of individuals with the disease. Over time this can result in serious damage to the heart, blood vessels, eyes, kidneys, and nerves. There are two key types of diabetes classed as Type I (pancreas produces very little to no insulin) or Type II (body becomes insulin resistant or fails to produce enough insulin). A link between diabetes and bacteria has been established with both diabetic mice and humans containing increased plasma levels of lipopolysaccharide (LPS), a component of Gram-negative cell walls (Cani et al., 2007; Creely et al., 2007). LPS has also been shown to impair glucose metabolism in mice (Creely et al., 2007). Furthermore, both Type I and Type II diabetes have been linked with the GI Tract microbiome (Larsen et al., 2010; Brown et al., 2011).

In Type II diabetes, metagenomics has shown an alteration to the gut microbiome compared to healthy controls (Larsen et al., 2010). Metagenomic studies within Chinese and Swedish cohorts showed markedly different bacterial composition of the gut microbiota at the species level but much like within obesity studies showed similar functionalities between healthy and diabetic microbiomes (Karlsson et al., 2013b). A lower abundance of butyrate-producing bacteria, which are known to be anti-inflammatory (Rivière et al., 2016), were observed in patients with Type II diabetes compared to healthy controls (Wang et al., 2012a; Karlsson et al., 2013b).

Type I diabetes has strong genetic links (Steck and Rewers, 2011) but more recent research has increased the evidence of environmental factors relating to the disease (Harrison et al., 2008). One metagenomic study into children with Type I diabetes found reduced bacterial diversity compared to controls (Brown et al., 2011). Furthermore, an altered serum metabolome was seen in children who go on to develop Type I diabetes compared to those that do not with many of the metabolites microbially regulated (Orešič et al., 2008).

Dental caries and gingivitis

Dysbiosis of the oral microbiome has been associated with multiple oral health issues including tooth infection (dental caries (Gross et al., 2010) and endodontic infections (Munson et al., 2002)) as well as gum related infections (periodontal disease (Huang et al., 2011) and periodontitis (Costalonga and Herzberg, 2014)).

Dental caries result from the dissolution of tooth structure resultant from acid produced from the fermentation of carbohydrates by oral bacteria (Walsh and Walsh, 2006). Correspondingly, the level of carbohydrates within the diet and the composition of the oral microbiome have been shown to impact development of dental caries (Jensen, 1999; Caufield et al., 2015). A number of commensal bacteria within the oral cavity are capable of producing acid from carbohydrates (Takahashi and Nyvad, 2011; Wade, 2013), however *Streptococcus mutans* and *Lactobacillus* spp. are known to continue producing acid from carbohydrates under acidic conditions (Caufield et al., 2015) so exacerbating the rate of tooth decay. Other bacterial genera implicated in the development of dental caries include *Bifidobacterium*, *Propionibacterium* and *Scardovia* (Munson et al., 2004; Downes et al., 2011; Tanner et al., 2011; Kaur et al., 2013). Conversely, some members of the oral microbiome have been noted to raise the pH within the mouth via production of urea and arginine, offering a neutralizing effect so allowing homeostasis (Burne and Marquis, 2000). Endodontic infections result from the progression of dental caries to the tooth pulp (Persoon and Özok, 2017). Bacteria associated with these infections are typically anaerobic proteolytic bacteria (Munson et al., 2002). *Enterococci* are associated with endodontic infections (Portenier et al., 2003; Wang et al., 2012b); these grow well within the tooth pulp and outside of this habitat are usually outcompeted by the normal microflora.

Gingivitis is the swelling of gums which bleed either spontaneously or upon probing (Page, 1986). Gingivitis is known to arise from the increase in number of Gram negative and anaerobic species within dental plaque which commonly occurs due to poor dental hygiene (Wade, 2013). The increase in abundance of dental plaque and these species within it produce endotoxins and enzymes which result in the observed inflammation and irritation of gums (Ebersole et al., 2010), however there are no specific species currently associated with this disease. Periodontitis derives from the loss of attachment between gingivae and teeth resulting in a periodontal pocket which goes on to be heavily colonized by anaerobic bacteria and ultimately can lead to tooth loss (Wade, 2013). Unlike gingivitis there are specific bacterial species associated with the development of periodontitis. Those identified in by culture-dependent methods include *Porphyromonas gingivalis*, *Treponema denticola*, and *Tannerella forsythia* (Socransky et al., 1998). Those identified by culture-independent methods include *Eubacterium saphenum*, *Anaeroglobus geminates*, *Filifactor alocis*, *Porphyromonas endodontalis*, and *Prevotella denticola* (Kumar et al., 2003).

Skin diseases

In 2015 a study by Scher et al. evaluated the link between the gut microbiota and patients with psoriasis and the associated condition psoriatic arthritis (Scher et al., 2015). Psoriasis is a disease which results in red, itchy scaly patches of skin, whereas psoriatic arthritis is a form of arthritis (swollen joints) affecting individuals with psoriasis (Moll and Wright, 1973). Comparative to healthy individuals a lower relative abundance of several intestinal bacteria were identified using 16S rRNA sequencing analysis. Patients with psoriasis had gut microbiota with a lower abundance of *Parabacteroides* and *Coprobacillus* compared to healthy individuals (Scher et al., 2015).

Acne and skin ulcers have been linked to components of the skin microbiomes. Acne is a common skin condition causing spots and oily or inflamed skin. The bacterial species *Cutibacterium acnes* (formerly *Propionibacterium acnes*) has long been associated with this condition (Bojar and Holland, 2004), with the secretion of enzymes from this species known to cause local injury and inflammation (Perry and Lambert, 2011). Individuals with chronic skin ulcers (open wound on the skin), treated with antibiotics, were shown to contain a higher abundance of *Pseudomonadaceae* within the skin microbiome (Price et al., 2009). The same study found those with type II diabetic ulcers instead had greater levels of *Streptococcaceae*. Alterations within the skin microbiome are thought to potentially cause aberrant expression of cutaneous defense response genes (Grice et al., 2010).

Cancer

The connection between the human microbiome and cancer is well reviewed in literature (Schwabe and Jobin, 2013; Bultman, 2014; Rajagopala et al., 2017; Goodman and Gardner, 2018). The microbiome has been linked directly and indirectly to the development of certain cancers as well as being altered in the presence of cancers.

Specific bacterial species shown to be carcinogenic include *Helicobacter pylori* with gastric cancer (Lee et al., 2008; Lofgren et al., 2011), *Salmonella enterica* with gallbladder cancer and mucosa-associated lymphoid tissue (MALT) lymphoma (Welton et al., 1979; Caygill et al., 1994), as well as *Campylobacter jejuni* (Lecuit et al., 2004), *Borrelia burgdorferi* (Cerroni et al., 1997) and *Chlamydia psittaci* (Ferrer et al., 2012) which are associated with certain lymphomas. Various viral pathogens have also been associated with cancers such as human papilloma virus with cervical cancer (Crosbie et al., 2013), Epstein Barr virus and nasopharyngeal cancer (Young and Dawson, 2014) or Burkitt lymphoma (Brady et al., 2008), hepatitis B and C viruses and liver cancer (Ringelhan et al., 2017) as well as HIV with a variety of cancers such as Hodgkin's lymphoma, lung, mouth and throat, skin and liver cancer (Engels et al., 2008; Patel et al., 2008; Silverberg et al., 2009).

Although many of listed microbes are not common commensals, known commensals such as the colonic commensal (in mice) *Helicobacter hepaticus* have been shown to promote the development of hepatocellular carcinoma (Ward et al., 1994; Yang et al., 2013). *Helicobacter pylori*, a common commensal found within the gastric microbiome, is linked to several diseases when at high levels including peptic ulcer disease, MALT lymphoma, and gastric adenocarcinomas (Testerman and Morris, 2014). Individuals with *H. pylori* within the gastric microbiome (three of those analyzed) are found to have it as a dominant species accounting for $\geq 90\%$ (Andersson et al., 2008). *Enterococcus faecalis*, a commensal within the gut, is genotoxic to cells and can induce aneuploidy and tetraploidy in colonic epithelial cells (Wang et al., 2008). This in turn could promote the development of cancer by stimulating an exaggerated immune response, with previous literature demonstrating a link between the immune system and cancer (Karin and Greten, 2005; Karin et al., 2006).

The composition of the microbiome is equally altered by the presence of cancer. The bacterial species *Fusobacterium nucleatum* has been shown to be significantly enhanced in colon cancer tumor samples both when compared to healthy individuals or tissue adjacent to the tumors (Castellarin et al., 2012; Kostic et al., 2012). Comparison of gut microbiota in individuals with tumors compared to those without showed a lower abundance of both Bacteroidetes and Firmicutes compared to other *Fusobacterium*-rich malignancies (Kostic et al., 2012).

Autoimmune diseases

Autoimmune diseases are conditions which arise from an abnormal immune response to a normal body part. A number of autoimmune conditions have been associated with the human microbiome including arthritis (Scher and Abramson, 2011) and inflammatory bowel disease (Halfvarson et al., 2017).

Inflammatory bowel diseases (IBD), namely ulcerative colitis and Crohn's disease, are chronic conditions involving the inflammation of the gut (Ishihara et al., 2009). Patients with IBD contain polymorphisms within the host bacterial sensor genes such as NOD2 (Hugot et al., 2001; Ogura et al., 2001) and TLR4 (Franchimont et al., 2004). There are also strong links between the microbiome and host immune responses with Th17 cell differentiation in mouse lamina propria reliant on segmented filamentous bacteria (SFB) (Cytophaga, Flavobacter, Bacteroidetes) (Ivanov et al., 2008) and polysaccharide A produced by *B. fragilis* mediating the conversion of CD4⁺ T cells to regulatory T cells (Round and Mazmanian, 2010). These studies suggest the emergence of IBD could therefore result from dysbiosis within the gut microbiome. Analysis of gut microbiota from individuals with ulcerative colitis compared to that of healthy individuals has shown significant difference in microbial composition, with reduced diversity and increased abundance of *Enterococcus faecium* and several Proteobacteria (Mondot et al., 2011). Specific members of Enterobacteriaceae have been shown to act in conjunction to increase the risk of developing ulcerative colitis (Garrett et al., 2010). Interestingly, treatment with antibiotics in early life has been linked to the development of Crohn's disease, suggesting that microbial perturbations could have an important role in the risk of developing Crohn's disease (Hviid et al., 2011).

Rheumatoid arthritis, a chronic idiopathic inflammatory condition, has been linked to alterations within the gut microbiota (Scher and Abramson, 2011). Studies in mice have suggested that the SFB results in local expansion of Th17 cells (Ivanov et al., 2009) which migrate to peripheral immune compartments and activate B-cells to antibody producing plasma cells (Cho and Blaser, 2012). Antibody production has been linked to immune-mediated destruction of joints, such as that observed in rheumatoid arthritis (Scher and Abramson, 2011). Psoriatic arthritis (PsA), a type of arthritis linked to patients with psoriasis, has also been associated with perturbations within the gut microbiota (Scher et al., 2015). Individuals with PsA were found to differ in bacterial compositions compared with healthy counterparts with the following showing greatest variation *Akkermansia*, *Ruminococcus*, and *Pseudobutyryvibrio* (Scher et al., 2015). The altered microbiome composition shares strong similarities with those observed in individuals with IBD, with both Ruminococcaceae and *Akkermansia* underrepresented in both PsA and IBD patients compared to healthy microbiomes (Willing et al., 2010; Vignani et al., 2012; Rajilić-Stojanović et al., 2013).

Conclusion

The human microbiome is the symbiotic association of microbes with the human body and is comprised of a plethora of microbial organisms including bacteria, viruses, eukaryotic microbes, and archaea. The importance of the composition and diversity within the microbiome has been explored in terms of both determining health and in the development of disease. Most research has focused to date on the bacterial populations, with recent years starting to see an increase in the characterization of eukaryotic microbiomes (Parfrey et al., 2011; Miller, 2016; Laforest-Lapointe and Arrieta, 2018) and viromes (Manrique et al., 2016; Carding et al., 2017; De Sordi et al., 2017). The NIH Common Fund Human Microbiome Project, launched in 2008, has allowed for the analysis of five body sites from large number of healthy adults. It has provided a wealth of information regarding the 'healthy' microbiome and >2200 reference strains. One key aspect to studying the microbiome has included establishing the diversity of microbial populations within different body sites and how varying confounding factors alter these including gender, diet, geography, time, and even personality traits. The importance of each of these factors has been shown to vary and furthermore it is virtually impossible for one to be truly studied in isolation. There have been some factors which have outweighed the importance of others such as the effect of diet on the gut microbiota.

The technologies for determining microbial diversity has changed over the years from culture, PCR, and gel-based methods to amplicon sequencing and more recently metagenomics, metabolomics, and meta-proteomics. Bias can occur across sampling and analysis methods used with distinct advantages and disadvantages to each. Standardization of protocols and study designs have been widely suggested to allow for better cross-sectional analysis of microbiome research (Goodrich et al., 2014; Poussin et al., 2018; Greathouse et al., 2019). The inclusion of multiple methods within a single study would also serve to produce a more complete picture of the microbiome and its role in human health.

Dysbiosis of the human microbiome has been affiliated with the development of various diseases including obesity, diabetes, as well as infectious and autoimmune diseases. The impact of the dysregulation of the microbiome can result in disease directly by reducing competition with pathogenic microbes or indirectly by the activation of the immune system. A key question to ask when analyzing the impact of these studies is whether the observed results are the cause or an effect of the disease. The case for it being causative can be supported by consistency in results, biological plausibility, and strength of association. Furthermore, as discussed earlier within this chapter there are many confounding factors in determining the diversity and composition of the microbiome, research into disease association with the microbiome requires ample controls to account for all confounding factors.

Introduction to chapter

At its most basic level microbial (both bacterial and fungal) growth is the division of a single (parent) cell into two (daughter) cells (Walther and Wendland, 2003). The process is named cytokinesis and is tightly regulated, with multiple redundant systems controlling it. Cell division is also tightly linked to other essential cell process such as DNA replication, spatial organization of cells, maintenance of their shape and size, and cell membrane and wall synthesis. This interconnectedness and regulation allow microbial populations to be maintained over multiple generations. Although bacterial and fungal species belong to two different kingdoms of life, much of their basic cell division principles remain similar, at least at a functional level. As such the term “microbial” is used within this chapter when discussing principles which are conserved in both bacterial and fungal organisms, with the two terms “bacterial” and “fungal” being used when discussing aspects of cell division which are specific to each kingdom.

Microbial growth and its control is an especially important driver of pathogenicity. Barreto et al. (2006) defined the term infection as “the entrance and development of an *infectious agent* in a human or animal body, whether or not it develops into a disease”. Such persistence would not be possible without the infectious agent being able to not only persist within the host, but also expand and/or maintain its population. Experimentally, microbial growth is a particularly useful output which can be easily and rapidly measured. Within the lab populations are typically cultured planktonically (i.e., suspended in broth) and with gentle shaking to ensure good aeration. Microbial growth medium is typically rich, with an excess of nutrients to support rapid population expansion. Under such conditions bacterial populations can expand rapidly, for example it is often quoted that under such conditions *Escherichia coli* populations can double every 20 min (Gibson et al., 2018). It must be recognized that this growth type, although very useful for microbiological investigations, is not typical outside the laboratory (Jaishankar and Srivastava, 2017).

In natural habitats nutrients are typically limited and there is intense competition for both nutrients and habitat. As such doubling times are significantly longer than described for lab grown planktonic populations. One recent study showed that within the gut environment *E. coli* had a doubling time of 15 h, compared to just 30 min under laboratory conditions (Gibson et al., 2018). Single species populations are also uncommon outside the laboratory. Instead, microbes commonly form “biofilms,” complex interspecies or even inter-kingdom populations which are anchored and surrounded in a self-produced extracellular matrix (Costerton, 1999; Hall-Stoodley et al., 2004).

Despite the uncommonness of rapidly growing planktonic populations outside the laboratory, measurement of growth underpins much of our understanding of microbial persistence, metabolism, pathogenicity and antimicrobial compound efficacy. Knowledge of microbial growth and division systems can lead to novel treatment strategies for combating infectious agents and increasing the lifespan of perishable goods. Accurate measurement of growth is important in testing antimicrobial treatments. There are multiple methods of measuring both microbial growth and population viability, the most common of which will be briefly described here along with their advantages and disadvantages. Typically, microbial growth is measured at the population levels, with little knowledge of the destination of single cells. However recent advances in technology have begun to allow investigation of gene expression, protein production and metabolism of single cells (Rosenthal et al., 2017).

This section will focus mainly on division of unicellular organisms, in particular bacterial species. The growth and division of fungal species is closely related to other eukaryotic species and detailed overviews of their cell cycles and division can be found in most molecular cell biology text books, for example Alberts et al. (2015). The chapter will initially discuss the phases of growth, before moving to a description of the major methods of population measurement which are used within the laboratory. We will then provide an overview of the molecular mechanisms involved in bacterial and fungal cell division along with some examples of atypical growth. Finally, we will describe three mechanisms of controlling population expansion, utilized by either the microbes themselves or via human intervention.

Unicellular growth (i.e., growth of bacteria and yeast—Binary fission)

Binary fission and the stages of population growth

Unicellular organisms (like bacteria, yeast and archaea) typically grow using a method called binary fission. Here each single cell (mother cell) expands, replicates its genetic material, and divides into two cells (daughter cells). In this way, each time a new generation is produced the population doubles (Fig. 1A).

Growth by binary fission is controlled by the availability of nutrients, space and environmental conditions. Nutritional and environmental factors are rarely optimum, slowing growth from the outset. In turn, binary fission also rapidly depletes nutrients and oxygen, regulating the pace of growth and causing it to further slow. Microbial growth within a closed system typically follows four phases: lag, log/exponential, stationary and death. These can be visualized as shown in Fig. 1B. and are described in detail in sections “Lag phase”, “Log/exponential phase”, “Stationary phase” and “Death phase”.

As well as understanding growth on a population scale, each cell undergoes a series of tightly regulated phases during its growth cycle. These cycles are named G (growth) 1 phase, S (synthesis) phase, G2 phase and finally M (mitosis) phase. G1 is a period of time in which the cell is actively growing in size, S phase encompasses the stage in which DNA and other cellular components are synthesized. Finally, G2 is a second period of growth, allowing the mother cell to become large enough to successfully divide into two daughter cells via mitosis. In addition to the four phases cells are able to move from an actively replicating cell cycle into “G0.” Cells in G0 are not actively replicating but still metabolically active. The ability to move from the cell cycle into G0 is particularly important for unicellular organisms, or static populations.

Fig. 1 In optimum growth conditions microbial populations can rapidly expand. An example of binary fission is provided (A) showing the rapid population expansion over five generations. (B) describes a typical microbial growth curve, highlighting the four stages of microbial growth.

Lag phase

When microbes enter a new environment, they require time to sense the new environmental and nutritional conditions, upregulate relevant genes and produce proteins. During this time little growth is observed. The period of time that lag phase lasts is dependent on not only on species but also the conditions and stresses encountered (Hamill et al., 2020). In rapidly growing organisms such as *E. coli* the lag phase is relatively short in duration whereas for slower growing bacterium such as *Mycobacterium tuberculosis* lag phase can last for a period of several days (Von Groll et al., 2010).

Log/exponential phase

During this phase populations are growing rapidly, typically via binary fission. During log phase the cells are highly metabolically active and dividing rapidly, increasing population density quickly and, in the case of some pathogenic species, causing overwhelming infection. In an open system, where nutrients are continually replaced and toxic products removed, exponential growth continues until no more physical space is available. However, nutrients within a closed system (for example an aliquot of broth or agar plate) are rapidly used up by the expanding population and toxic waste products (such as ethanol) rise. Many experimental systems use cells which are in log phase. Rapid population expansion is particularly useful when assessing the effect of antimicrobials on microbial populations, since it allows easy measurement of any inhibition compared to untreated, positive controls.

Stationary phase

During stationary phase the population is static, with the number of cell deaths and cell divisions balancing each other. Most of the population are still metabolically active, but population expansion is slowed and the majority of the microbes within the population are not undergoing division. In an open system once stationary state is reached this becomes the steady state of the microbial population and can be maintained for prolonged time periods. In closed systems a period of stationary phase is followed by death phase once nutrients are depleted to a critical level.

Death phase

In death phase the viability of the population decreases as nutrients become scarcer and toxic products accumulate. Microbes are no longer able to replicate due to both the lack of nutrients and cellular damage incurred. Death phase may be reversed by replenishment or replacement of the growth medium although, this is not possible if the damage to the cells is too extensive. Typically, medium replenishment will move microbes back through the growth cycle, with a short lag phase while the cells carry out repair to damaged systems and up regulate metabolic and replicative genes followed by a log phase until nutrient depletion again reaches a critical stage, and the cells can no longer replicate exponentially.

Measurement of microbial growth

Accurate measurement of populations is important as many experimental microbiological techniques require initial inoculums at specific cell concentrations and/or at specific points in their growth cycle. Commonly, growth is considered at the population level although it is important to remember that individual cells will be at different stages of the cell cycle. Not all the techniques discussed here are suitable for all microbial species and researchers must carefully consider the pros and cons of techniques before making a choice. It is not uncommon for more than one method to be used in parallel. Here we have provided an overview of four commonly used techniques, along with some information of both positive and negative aspects of the techniques to assist researchers in their choice (an overview of the techniques is presented in Table 1).

Optical density

Optical density (OD) is a method of quantifying microbial growth in relation to the turbidity of an inoculum, i.e., its optical density. An assumption is made that the number of microbes within any suspension is directly proportional to the turbidity of the culture and as such, dilution to a set optical density represents a specific microbial concentration. Density measurement is widely used in research and clinical labs as it provides a rapid and inexpensive method of adjusting microbial suspensions to set concentrations. The technique is particularly powerful when used in conjunction with cell counting methods, allowing researchers to rapidly dilute suspensions to an estimated concentration using optical density and then confirm the estimate was correct using cell concentration counting.

McFarland developed a method of preparing suspensions of set turbidity, to which microbial inoculum of unknown concentration could be compared (McFarland, 1907). These “McFarland Standards” have equivalent density to bacterial cultures meaning a researcher can prepare a standard concentration of bacteria without the need for counting (Lahuerta Zamora and Pérez-Gracia, 2012). Typically, measurement is done either by comparing the density of inoculum to pre-prepared standards or by using a spectrophotometer measuring light scatter.

Table 1 Overview of microbial quantification techniques.

Name	Description	Positive aspects	Considerations
Cell count	Initial inoculum is serially diluted, plated and allowed to grow. Counts of the number of colonies grown directly relate to the viable microbial concentration in the initial inoculum	The method allows direct enumeration of inoculum without confounding factors such as debris or slowed metabolism. The method is commonly used, allowing easy comparison of data to previously published examples.	Time must be allowed for colony growth meaning instant assessment of inoculum concentrations is not possible. The method also requires a greater number of materials and reagents than other common methods.
Optical density	The concentration of an inoculum is directly related to its turbidity. As such, dilution of an inoculum to a specific turbidity should provide a specific microbial concentration	Instant method of determining concentrations. It requires minimal materials and equipment.	The method is based on turbidity so care must be used to ensure the microbe concentration-turbidity relationship is known in advance and confounding factors (i.e., debris) are limited.
Viability staining	Dyes either convert to a colored solution upon metabolism or bind selectively to viable cells	There is a wide range of viability stains available, so the methods are highly adaptable to budget, application and specific research need.	Viability dyes can be influenced by the growth phase of the inoculum, leading to over/under estimation of populations. Some are also expensive, require specialist equipment to measure or long incubation periods before reading
Quantification by qPCR/sequencing	Conserved/variable DNA regions are amplified and quantified from whole communities to enumerate the gross community or specific members.	The technique requires no culture and can be used on highly complex communities. In combination with sequencing, it can give significant information about the community members, their genes and biology	Many steps in the process have a bias and expertise is needed to interpret data correctly. Sequencing is relatively expensive, time consuming and requires specialist equipment (although qPCR only techniques much less so).

It should be noted that although turbidity measurement can be linked to bacterial density it is not necessarily a direct correlation. Turbidity can be impacted by the presence of debris, microbial cell size, extracellular products and/or microbial clumping within the sample (Zapata and Ramirez-Arcos, 2015). Some bacterial species, such as *Bdellovibrio* sp. are so small that they are unable to register a density measurement. In contrast, yeast species such as *Candida* sp. are much larger than *E. coli* and so will have much lower cell number than *E. coli* when diluted to the same McFarland standard. Density measurements also give no indication of growth stage or viability of the sample.

Cell counting

Microbial growth counts provide a highly accurate estimate of the microbial population, which is not confounded by the presence of debris or dead cells. One of the most accurate ways of determining microbial numbers in clonal population is to count a subset of the microbial population and scale that number up to give a concentration for the whole population. Typically, this is done by producing a series of dilutions (serial dilutions are usually logarithmic, i.e., 10-fold). The dilutions are then added to agar and incubated in optimum growth conditions to allow microbial growth and colony formation (Fig. 2).

It is assumed that each single microbe within a dilution will grow by binary fission to produce a clonal colony. Colony counting methods express the concentrations as the number of colony forming units in each mL of the initial microbial culture or “CFU/mL.” The term “colony forming unit” is used in preference to a cell/mL value since although the assumption is that each colony on the plate is derived from a single cell, this is not directly known. To extrapolate the total number of cells within the starting inoculum the following formula is used:

$$\text{CFU/mL} = \frac{\text{Number of colonies} \times \text{dilution factor}}{\text{Volume spread on agar plate}}$$

Many videos are available online demonstrating colony counting methods and how to calculate CFU/mL.

Although colony counting methods are commonly used and considered to be one of the best methods of estimating inoculum concentrations, they do have some negative aspects which should be fully considered before use. It is important to have some understanding of the growth dynamics and phenotype of the species to be worked with before counting. For example, if the species to be worked with produces aggregates which cannot be separated then it is very likely that any CFU/mL values will underestimate the actual number of viable cells. Some bacterial species which have a mucoid or swarming phenotype, for example *Pseudomonas aeruginosa* and *Proteus mirabilis* respectively, will also be difficult to count accurately since they do not produce well defined and separated colonies when grown on some agars. Similarly fungal species which form complex multicellular bodies or hyphae are difficult to count, although this technique can work well with species, such as yeast, which have a unicellular, non-hyphenated growth stage. Finally, methods for determining CFU/mL are time consuming, requiring a period of incubation to allow visible microbial growth and require a large number of agar plates. This can be mitigated slightly using direct methods such as counting cells within a hemocytometer, but again this is not suitable for all species—in particular those which are very small or motile.

Fig. 2 Overview of a basic method of counting the number of colony forming units within a population.

Viability staining

Various dyes can be used to determine the viability of a microbial population, with viability being both a measure of concentration and population growth phase. In their most basic form viability dyes are altered by metabolic activity or able to preferentially enter only live or dead cells, leading to the conversion of the dye or selective labelling of specific populations. Quantification can be colorimetric, fluorescent or luminescent, with the measurement mechanism linked to the specific dye used. The choice of dyes is restricted only by the experimental system, output method and budget. Here an overview of commonly used viability stains/techniques is given.

High throughput-based dye methods

Tetrazolium salt-based dyes are commonly used as they are cheap, readily available from suppliers and easily measured colorimetrically. Examples include: 2,3,5-Triphenyltetrazolium chloride (TTC) which changes color from clear to a red solution (Brown et al., 2013), 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl tetrazolium bromide (MTT) changing color from yellow to purple solution (Benov, 2019) and sodium 3,3'-[1-[(phenylamino)carbonyl]-3,4-tetrazolium]Bis[(4-methoxy)-6-nitro]benzene sulfonic acid hydrate (XTT) which changes from yellow to red solution (Xu et al., 2016; Pérez et al., 2010). Another commonly used dye is resazurin, which develops from a deep blue to bright pink color when exposed to metabolically active cells. Resazurin relies on redox reactions to stimulate the color change, making the dye also useful as an indicator of anaerobic conditions. It can be quantified fluorescently, although the obvious color change makes viability easy to see by eye. Due to the dramatic color change resazurin is often used in antimicrobial susceptibility assays, allowing researcher to clearly see the exact concentration at which a compound becomes inhibitory to the population. Finally, luciferase dyes luminesce upon interaction with ATP, a reaction which can be quantified by spectrophotometers able to measure luminescence.

As with all the techniques discussed here the use of viability dyes is particularly powerful when used in combination with other microbial growth techniques. For example, when populations move from lag to log or log to stationary phase there may be little difference in CFU/mL or turbidity, but metabolic activity will alter significantly at these transition points and can be tracked by using both metabolic dyes and cell counts. Although tetrazolium salts and resazurin are relatively cheap and stable at room temperature some other fluorescent and luminescent dyes are expensive and require storage in chilled or frozen conditions. Fluorescent and luminescent measurement also requires specialist consumables, such as black or white microtiter plates, and spectrophotometers able to measure the specific light spectrums required. This can make them too costly for routine measurement of cell growth, although for more specialist or focused techniques, such as microscopy and flow cytometry, they are a powerful tool.

Microscopy/cytometry-based viability dyes

Some dyes are also able to distinguish between live and dead cells using a combination of two dyes, one of which typically binds DNA and will penetrate all cells, examples include propidium iodide and 4',6-diamidino-2-phenylindole (DAPI), and a second dye which binds only to viable cells. Live/dead staining can be useful to determine total and viable numbers in a population and is suitable for use with both microscopes and flow cytometers. Live/dead dyes are frequently used when assessing the efficacy of

antimicrobial treatments and can give rapid information on both total microbial numbers and population viability. They can also provide information about the fate of individual community members something which is impossible when using the other techniques mentioned sections “Binary fission and the stages of population growth” and “Lag phase”.

Quantification of genetic material

All the techniques mentioned above require laboratory culture of micro-organisms for a period, however the vast majority of known microorganisms are not able to be cultured, so could not be quantified by standard techniques. Examples include soil, marine and gut microbiome communities. To investigate such communities, molecular techniques can be used. Commonly these techniques involve amplifying “universal” DNA fragments, such as the 16S rRNA gene in bacteria or internal transcribed spacers (ITS) in fungal species. These sequences contain both conserved and variable sequences. The conserved sequences are “universal,” meaning that primers designed to bind in these areas will be able to bind to DNA from a wide range of species. In contrast amplification of variable DNA regions allows greater specificity, allowing investigators to identify what organisms are present and their proportion within a community. At the most basic level primers can be used in combination with quantitative PCR (qPCR) to determine either the total size of a community or subsections (Jian et al., 2020). The technique is commonly combined with next generation sequencing, allowing a single set of primers to be used to amplify DNA from the whole community. This mix is then sequenced and *in silico* analysis used to match the sequences back to specific genus or species (Tringe and Hugenholtz, 2008). As the cost of sequencing has decreased, 16S rRNA sequencing can be replaced by Shotgun Sequencing, which sequences all the DNA within a community, allowing functional information such as antimicrobial resistance to also be discovered. Shotgun sequencing also allows all members of the community, whether bacterial, viral or eukaryotic to be identified in a single step.

Although these methods are very powerful and have significantly improved our knowledge of the diversity of microbial communities, there are some considerations researchers should think about before beginning a study. Firstly, it is not possible to determine if all the DNA present in a sample originated only from viable organisms. DNA is a very stable structure and able to persist in the environment. As such using DNA for enumeration can be difficult unless the amount of non-viable organism DNA present in the sample can be accurately estimated. All DNA extraction methods and primers have a bias towards specific organisms. For example, Gram-positive organisms are more difficult to lyse than Gram-negative ones and as such less Gram-positive DNA may be present, even if they were present in equal numbers in the originating community. As such, researchers must recognize that their data will be skewed, with some community members being under- or over-represented as a result of the choice of DNA extraction method, primer design and amplification (Poretsky et al., 2014). It is very important to understand the bias of the methods chosen in order to give a correct interpretation of data. The number of copies of the 16S rRNA gene in an organism is also variable, again potentially leading to overrepresentation of particular members of the community (Kembel et al., 2012). Finally, techniques which including sequencing, although powerful, are costly and take several weeks to complete, so would be unlikely to be chosen for routine enumeration. They also require a significant element of *in silico* processing, which again can introduce bias or be open to false interpretation. Identification of organisms is carried out by software which matches sequences provided to online, publicly available, databases. If sequences from an organism are not present in the database, or the sequence quality obtained is poor, matches will not be found, and no identity assigned. Experimental design is particularly important in these types of studies and there are many online resources and training courses to help researchers.

Bacterial division

Our knowledge of microbial division largely comes from the study of division in two model organisms: the Gram-negative *E. coli* and *Bacillus subtilis*, which is Gram-positive. As with the study of many other molecular mechanisms, these two organisms were utilized because they are genetically tractable and multiple molecular tools have been developed to work effectively with them. It should be noted that neither of the organisms present a particular “representative” model of either Gram-negative or -positive organisms. Both organisms are rod shaped and as such do not provide an effective model of the growth of other bacterial shapes, such as coccus or spiral shaped species such as *Staphylococcus* sp. and *Campylobacter* sp. Despite their limitations as model organisms, the action of binary fission is largely conserved across bacterial and archaeal species and as such information drawn from these two species can be applied to other bacterial species.

In its simplest form, binary fission must involve the formation of a ring (called the Z ring) in a mid-point of the parent cell after replication of the cellular components is completed. This ring then constricts, and finally separates, forming two daughter cells (Fig. 3). It therefore follows that, if the basic mechanism of division is the same then several the major microbial division proteins may also be conserved. This was found to be the case; the major protein forming the Z ring, a protein called FtsZ is highly conserved across all bacteria and archaea. FtsZ is also very similar in structure to tubulin, which is a major eukaryotic cytoskeleton component, suggesting that the evolution of this protein occurred at a very early stage in the evolution of life (Erickson, 1997).

Differences do however occur in the mechanisms supporting ring formation and its positioning. Although many of these mechanisms are again conserved across species, there is a greater degree of redundancy, so species may not contain copies of all the genes. In many species inactivating the genes involved in, for example, positioning of the Z ring does not lead to complete defect in the cell division process and, as in the case of nucleoid occlusion systems (described in detail in section “Nucleoid occlusion”), several genes must be inactivated before clear phenotypes are discovered (Wu and Errington, 2004; Bernhardt and De Boer, 2005).

Fig. 3 Overview of the process of cell division and the major steps.

In this section some of the major mechanisms controlling the cell division machinery will be described, with a focus on proteins identified as important to *E. coli* and *B. subtilis* since these are among the best studied (Errington et al., 2003). Although the Z rings formation and regulation is carried out by proteins of similar function in different microbial species, except for FtsZ these proteins may not have homologous amino acid sequences, being functionally rather than structurally similar.

FtsZ and the Z ring

FtsZ is a homologue of tubulin, the protein which in eukaryotes is involved in cytoskeleton structure. FtsZ is highly conserved and present in all bacteria and archaea. When FtsZ proteins are allowed to assemble *in vitro* (i.e., outside of the cellular environment) they assemble into long fibers (Mukherjee and Lutkenhaus, 1994). The fibers assemble at a specific point of the cell, typically the mid-point within elongated, rod shaped, cells, and form a ring structure closely associated with the inner surface of the cytoplasmic membrane. This structure is called the Z Ring and is the fundamental structure required for cell division. Assembly of the Z ring recruits other proteins involved in cell division (the divisome) to the area. The Z ring is also the point at which the cell wall begins to invaginate, due to constriction of the Z ring. The wall invagination eventually leads to the division of one cell into two daughter cells. Key members of the divisome are described in Table 2.

The positioning and formation of the Z ring is highly regulated, since its incorrect positioning or poor timing of division could lead to serious viability problems within the daughter cells. The Z ring must be placed away from nuclear material and division must be timed so that the cells are able to maintain not only their correct volume and shape but also genetic material and (in the case of eukaryotic organisms) organelles. The Z ring and divisome are typically assembled in two stages. Initially the FtsZ proteins assemble and begin to recruit “core” divisome proteins to the structure. There is then a lapse in activity as the cell cycle continues and the cell expands to the volume necessary to produce two daughter cells (G2 phase). Finally, when the cell reaches the desired size and volume, the second stage of recruitment occurs, and the parent cell divides. The major proteins involved in the divisome, and key cell division processes are listed below in Table 2. Although multiple proteins have been identified as having a critical role in cell division, there is still little definitive information about the exact role many play.

Regulation of Z ring formation and positioning

The regulation of cell division is as important as cell division itself since division at the wrong time in the cell cycle or in the wrong part of the cell could lead to irreparable damage and cell death. As such, just as is the case with the cell division apparatus, the cell division regulatory systems are highly conserved. Here we will discuss two of the most common regulatory systems: nucleoid occlusion and Z ring positioning. As with the cell division apparatus, these systems have been most closely studied in model organisms such as *B. subtilis* and *E. coli*, but homologues of the major proteins involved are present in a wide range of bacterial species.

Nucleoid occlusion

Nucleoid occlusion is a system which inhibits placement of the Z ring in the vicinity of nuclear material (Wu et al., 2009). This means that the nuclear material is remote from the area where the Z ring forms and so cannot be damaged during the separation of

Table 2 Table of proteins typically involved in formation and regulation of the divisome.

Name	Role	References
<i>Core divisome</i>		
FtsZ	FtsZ units assemble into protein filaments which form the Z ring. This provides a point of anchor for constriction of the membrane, separating the cell into two daughter cells. FtsZ is closely related to the eukaryotic protein tubulin.	Silber et al. (2020) and Margolin (2005)
FtsA	Closely related to the eukaryotic protein actin, FtsA binds to the FtsZ polymers and secures them to the cytoplasmic membrane.	Ozyamak et al. (2013) and Chen et al. (2017)
ZipA	Inner membrane protein which also plays a role in securing the Z ring to the membrane. There is some redundancy between the role of FtsA and ZipA, with both providing a similar end function (via a different mechanism).	Chen et al. (2017) and Hale and De Boer (1997)
FtsK	FtsK (and its <i>B. subtilis</i> homologue: SpoIIIE) are involved in positioning chromosomes so they can be separated and translocated to the daughter cells. FtsK localizes at the septum site and assists in recruiting other divisome components.	Stouf et al. (2013) and Besprozvannaya and Burton (2014)
FtsQ, FtsL and FtsB	Transmembrane proteins which form the FtsQBL complex. Role of the complex is still poorly understood but hypothesized to be part of the Z ring scaffold.	Choi et al. (2018)
FtsW	Transporter protein which exports Lipid II, a cell wall component, allowing expansion of the cell wall during elongation.	Mohammadi et al. (2011)
FtsI	Also named Penicillin binding protein 3. FtsI forms a complex with FtsW and has a role in peptidoglycan biogenesis. This allows expansion of the cell wall and subsequent elongation of the cell.	Marmont and Bernhardt (2020)
MatB, ZapA, ZapB	Responsible for chromosome separation and anchoring the chromosome to the Z ring via the replication terminus region.	Männik et al. (2016)
XerC, XerD	Tyrosine recombinases involved in separation of replicated chromosomes. Their activity is coordinated with that of FtsK.	Castillo et al. (2017) and Spiers and Sherratt (1999)
<i>Z ring position regulation</i>		
Noc/SlmA	DNA binding protein. Noc is a major factor in effecting nucleoid occlusion and inhibiting division (SlmA is the <i>E. coli</i> homologue). Noc is able to bind to both DNA and FtsZ, disrupting normal Z ring formation when bound to both.	Tonthat et al. (2011)
MinC	Interacts directly with FtsZ to destabilize the Z ring and inhibit its formation.	Park et al. (2018)
MinD	ATPase which recruits MinC to the site of the bacterial membrane. MinC cannot begin to oscillate without MinD.	Margolin (2001)
MinE	MinE oscillates between the cell poles, moving the MinC/D complex with it. Due to the oscillation more MinE accumulates at the poles, along with the MinC/D complex it accompanies. This leaves the center of the cell free for binding of FtsZ and limits the potential of FtsZ to bind away from the center of the cell.	Hu and Lutkenhaus (1999)
MinJ and DivIVA	Within the <i>B. subtilis</i> min system MinE is replaced by these two proteins. The proteins form a complex which allows MinC/D to oscillate, accumulating at the cell poles and limiting the potential of Z ring formation away from the center of the cell.	Errington and Wu (2017)

This list is not exhaustive but gives those major proteins identified to be involved in *E. coli* division.

the daughter cells. Within the division cycle the chromosome, and associated genetic material such as plasmids, are replicated and then moved to opposite poles of the cell. This movement allows the center of the cell, where the Z ring typically forms, to remain relatively clear. The physical distancing of the genetic material from the area of division helps to ensure that genetic material is not damaged or lost during separation of the two daughter cells. In *B. subtilis* the protein controlling nucleoid occlusion is named Noc, the *E. coli* homologue is SlmA. Noc/SlmA can bind directly to FtsZ and the bacterial chromosome via specific DNA sequences (Wu and Errington, 2004; Wu et al., 2009). When bound to both DNA and FtsZ Noc is able to interfere with normal Z ring formation (Tonthat et al., 2011). This double binding means that if DNA is within the vicinity of the Z ring formation site the Z ring cannot form, limiting the potential for chromosomes damage during Z ring contraction and daughter cell separation.

As with many of the systems involved in cell division, nucleoid occlusion does not appear to be essential for position of the Z ring, at least in *E. coli*. In cells where no nuclear material is present (anucleate) the Z ring still formed at or near the midpoint of the cell, suggesting other mechanisms also support Z ring localization (Sun et al., 1998). One such system involved in the positioning of the Z ring is called the Min system.

The min system

The Min proteins form a negative regulation system which allows correct positioning of the Z ring in the center of rod-shaped cells. In *E. coli* three proteins (MinC, MinD and MinE) form the Min system whereas in *B. subtilis* there are four major proteins (MinC, MinD, MinJ and DivIVA) (Singhi and Srivastava, 2020). MinC and MinD form a complex, named MinCD, which is preferentially positioned at the poles of the cell. This positioning leads to a concentration gradient of MinCD, with the poles having the highest concentration of the complex. This presence of this complex inhibits binding of FtsZ, thereby localizing FtsZ binding (and therefore Z ring formation) near the center of the cell, away from the nucleoid containing poles. When minC and minD are

inactivated in *B. subtilis* multiple Z ring structures form, although this effect can be mitigated by providing minimal nutrients, indicating the Min system is also in part redundant and works alongside other, currently unidentified, systems (Levin et al., 1998).

Min systems can either be oscillating, moving continuously from pole to pole of the cell, or non-oscillating, where the protein complexes are near the poles of the cells (Taviti and Beuria, 2019). MinD and MinE are needed for oscillation. The *E. coli* min system contains all three proteins and is an oscillatory system, *B. subtilis* lacks the MinE protein and as such its system is non-oscillatory. As with many of the other proteins involved in cell division the Min system can assemble and function *in vitro*, with no additional cellular components present (Zieske and Schwillie, 2014).

Division in atypical organisms and circumstances

The majority of bacterial cells position their Z ring in the center of the mother cell and following cytokinesis two daughter cells are produced which are identical to the mother cell. The growth of cells is also typically initiated at the site of Z ring formation, with expansion occurring equally at both sides of the Z ring site. This however is not always the case, and some species are able to divide asymmetrically or expand in size from a single pole.

The genus *Mycobacterium* expands not from the central septum site, but from one of the cell poles. Regulation of the expansion sites position is still not understood, but position always appears to occur at the distal end of each cell (Baranowski et al., 2019). For species where heterogeneity is required in daughter cells then polar growth and division is particularly common. Since growth only occurs from one pole, rather than the site of septum formation, cell membrane and wall components are temporally separated, with the oldest parts of the cell wall inherited by the daughter cell. In cells elongating from the central septum both mother and daughter cells will contain a mix of new and old components. Although growth is polar in *Mycobacterium* sp. the Z ring is still positioned in the cells mid-point. The mechanism of this positioning is still not well understood since *Mycobacterium* sp. contain no nucleoid occlusion homologous genes and only a single, distantly related, Min protein (Baranowski et al., 2019).

Yet other bacteria produce two distinctly different daughter cells during division. Perhaps the best studied model of this is the aquatic Gram-negative species *Caulobacter crescentus*. When undergoing division this species produces one flagellated daughter cell, while the aflagellated mother cell remains tethered to a surface via a stalk. The *C. crescentus* lifecycle is particularly complex with cells changing function and morphology multiple times before successful division occurs. Cells initially have a swimming lifestyle, before attaching to surfaces via tether or stalk, losing its flagella in this process. Swimming cells are unable to begin DNA replication (Skerker and Laub, 2004). Once tethered the mother cell initiates cell division and enters a continuous cycle of producing flagellated daughter cells. Although the daughter cells cannot begin replication until they themselves are tethered their ability to swim allows them to explore the environment, only settling and becoming stalked mother cells when a suitable environment is encountered (Xu et al., 2020).

Finally, many bacterial species can form spores. Spores are produced by parent cells when conditions are unsuitable for growth. Spores are a highly resistant, dormant cell type which can persist in a vegetative state until local conditions are able to once again support growth. At this point the spore germinates, become metabolically active and initiating cytokinesis. *B. subtilis* is an example of a spore forming bacterium and much work has been carried out in this species to understand the basic sporulation apparatus. For a *B. subtilis* spore to be formed the mother cells first initiates asymmetrical cell division. Rather than forming in the center of the mother cell, during sporulation the septum is much closer to one pole, producing a much smaller daughter cell (termed a “forespore”). Septum formation and closure is not completed however, so the daughter cell is not released. Instead the mother cell engulfs the forespore, allowing it to mature within the cytosol. Finally, the mother cell undergoes a programmed lysis, releasing the spore (Tan and Ramamurthi, 2014). Sporulation is an important virulence factor utilized by several opportunistic pathogens. The ability to form spores allows bacteria to remain in an environment indefinitely without incurring a metabolic cost. *Clostridioides difficile* is a slow growing spore forming anaerobic member of the gut microbiome. In the healthy gut *C. difficile* is unable to outcompete other members of the microbiome, maintaining a small population. Its ability to form spores allows it to persist during antibiotic treatment, which dramatically reduces the abundance of other microbiome species. Following antibiotic treatment *C. difficile* spores quickly germinate and can become the dominant species within the gut, causing a range of gastroenteritis symptoms ranging from mild diarrhea to potentially fatal colitis (Shen, 2020). Infection is difficult to eradicate as further antibiotic treatment results in the production of spores, which again can germinate once antibiotic treatment is stopped. To date the most effective treatment for *C. difficile* infection is replacement of the gut microbiome via fecal transplant (Baunwall et al., 2020).

Fungal division

Fungi and yeast are eukaryotic rather than prokaryotic and as such have a similar cell division machinery and processes to other animal and plant cells. In depth information about the eukaryotic cell cycle and division can be found in standard cell biology text books such as (Alberts et al., 2015), but much of our understanding of the process comes from investigation in model yeast organisms such as *Saccharomyces cerevisiae*. In its most basic form fungal cell division follows the same process as that of bacterial cells, although different terminology is used for key components and processes. The mother cell must replicate its DNA (and in the case of eukaryotes organelles must also be multiplied), expand the size of the cell, form a septum (analogous to the bacterial Z ring) and then constrict and separate at this point until two daughter cells are formed. Yeasts and fungi are able to exist as both unicellular and multicellular forms, both requiring different cell division processes, with only the unicellular form discussed here. Cell division

is a highly choreographed process, with specific processes only occurring at set points in the cell cycle (described in Section “Unicellular growth (i.e., growth of bacteria and yeast—Binary fission)”).

Before entering G1 cells must commit to the division process, passing a checkpoint called “Start.” Once Start is passed the cell is committed to division and although the process can later be delayed at further checkpoints if key processes are not completed the cell cannot exit cell division once committed to the process. Following Start the cell moves through the cell cycle before finally separating into two cells at M phase. Progression through the cell cycle is controlled by the interaction of cyclins and Cyclin Dependent Kinases. Cyclins are so named because they are only expressed at specific points within the cell cycle. There are two major types of cyclin in *S. cerevisiae* G1 cyclins, regulating events in G1 and the initial commitment to cell division and B-type cyclins, which are usually expressed between Start and the end of M phase (Dörter et al., 2016). Size also plays a role in progression through the cell cycle, with cells not able to undertake S and M phase activities until they have reached specific mass (Berman, 2006).

As with bacterial cells, not all fungal species divide symmetrically. Again, *S. cerevisiae* is one such example. In this species most new cellular components created during each division cycle are inherited by the daughter cell, with the mother cell retaining older (and potentially damaged) molecules. This system of inheritance allows the population overall to remain healthy, with only the oldest cells containing any potentially damaged components (Manzano-López and Monje-Casas, 2020). Daughter cells are also smaller than the mother cell, requiring a prolonged G1 period to reach the size required for transition into S phase (Berman, 2006).

Limiting microbial growth

In vitro culture of organisms typically allows greater growth of microbial populations than they would experience in a natural setting. The conditions encountered by microbes when infecting a host are typically very nutrient deficient. Hosts deliberately limit the availability of nutrient such as iron to limit the potential for a microbial population to exponentially increase (Hershko, 1993). The immune system also constantly screens the host for the presence of microbes. If microbes, and particularly rapidly growing population of potentially pathogenic microbes, are encountered within tissues the immune system is rapidly activated, limiting the possibility of microbes to become established or cause symptomatic infections. Exponential growth is the exception rather than normality in nature. To maximize survival in these sub-optimal conditions most microbial species have sophisticated signaling, sensing and migration mechanisms. These systems allow them to sense not only the local environmental conditions, but gradients of nutrients and toxins and the density of the surrounding microbial population. Unlike the systems controlling cell division these systems are numerous, less conserved and often species specific.

Quorum sensing (QS)

QS is particularly important during infection as it is the mechanism by which population density is detected. QS systems are two-component systems comprising of both a small soluble marker which is secreted by the microbe and a cell wall bound receptor (Portnoy et al., 2000). The soluble marker is secreted by the cell and detected via the receptor. In areas of low diffusion or high population density there will be high levels of soluble marker present, conversely when few cells are present, or diffusion is rapid little marker will be available to bind to the receptors. In this way microbes are able to co-ordinate communal behaviors such as virulence factor production, sporulation, log phase growth and biofilm formation (Abisado et al., 2018). Alongside nutrient detection systems the QS system is also able to drive population expansion or a move to a stationary growth phenotype.

Biofilm formation

Biofilms are defined as attached microbial populations which are surrounded in a self-produced extracellular matrix (ECM) (Costerton, 1999). Biofilms typically contain more than one species of bacteria or fungus, with many containing a mix of fungal, bacterial and viral species. Since their discovery approximately 40 years ago they have been shown to be the primary lifestyle of microbes and are now known to be an important virulence factor. It is estimated that 65% of all infections and 80% of chronic infections involve biofilms (Jamal et al., 2018). Biofilms are such an important pathogenicity factor for several reasons. Firstly, the biofilms size limits the ability of phagocytic cells to engulf them. Since the biofilm cannot be engulfed host cells instead initiate a pro-inflammatory response, secreting cytokines and chemokines and causing further local tissue damage. Damage to the tissue surrounding the biofilm in turn releases more nutrients which can be utilized by the microbes within the biofilm. Secondly, the ECM has a protective function, limiting diffusion in and out of the biofilm. This property not only inhibits penetration of antimicrobials but stops diffusion of nutrients or communal goods such as β lactamase, an inhibitor of β lactam antibiotics. Finally, biofilms predominantly contain stationary phase organisms which means that large numbers of organisms can be sustained in an environment with limited nutrients.

Targeting microbial growth mechanism with antimicrobials

The term antimicrobial is a collective term for all substances which can limit the growth, replication and/or metabolism of microbes, be they bacteria, fungi or virus. They can be synthetically made or derived from natural products or cellular secretions. Although it may therefore seem obvious to state that all antimicrobials inhibit microbial growth, many of them specifically target

aspects of the cell division machinery. The cell division machinery is a particularly attractive target as these proteins are highly conserved within bacteria, but often are different to those found in Eukaryotic cells. This means that any drugs targeting cell division apparatus are likely to have broad spectrum activity, while also not proving toxic to the host (for a review see (Den Blaauwen et al., 2014)). Curcumin, a phenolic compound produced within the Turmeric root, was demonstrated to reduce expansion of a *B. subtilis* population with treated cells showing a filamentous (elongated) cell morphology (Rai et al., 2008). Further investigation highlighted the curcumin inhibited accumulation of FtsZ, stopping Z ring formation and initiation of cell division (Rai et al., 2008).

Several antibiotics also target the cell division machinery. For example, β lactam antibiotics, including Penicillin, limit the ability to expand bacterial cell walls, stopping the enlargement of cells prior to Z ring formation and division (Yocum et al., 1980). Quinolones target DNA replication mechanisms, specifically inhibiting the activity of DNA gyrase (Aldred et al., 2014) so that DNA cannot be efficiently translated. A note of caution must be sounded however as the majority of antimicrobials targeting microbial growth systems are most effective against rapidly growing bacterial populations. As discussed earlier, rapid (exponential) growth is not the normal mode of growth outside of the laboratory where environmental factors typically limit population expansion. As such antimicrobials inhibiting cell division may not be effective against slow growing or static populations, such as those found in biofilms. In these instances, antimicrobials which target essential cellular functions such as protein synthesis may be a more appropriate treatment choice.

Summary and conclusion

Within this chapter we have discussed binary fission and its key stages, the major systems involved in bacterial and fungal cell division and techniques commonly used for the measurement of microbial growth. Much of the cell division machinery is conserved across all prokaryotes. Many microbes also appear to utilize multiple checkpoints and regulatory mechanisms to ensure that cell division occurs smoothly and at the correct pace. Many of the proteins involved in cell division appear to be in part redundant, increasing the chance that division will occur without damage to the daughter cells. To date we have a detailed knowledge of how division occurs in model organisms however, there is still much to be discovered. Recent advances in genomics, transcriptomics and proteomics as well as microscopy have allowed us to begin to investigate fundamental biological systems, such as cell division, in individual organisms. This means that rather than measuring populations as a whole, the fate of single cells and their offspring can now be followed and modelled. This will provide a further insight into microbial growth, its control and the factors, both intrinsic and extrinsic, which control it.

Skin infections

Infections of the skin can be caused by bacteria, viruses, parasites and fungi and across the population they are extremely common, with an estimated 24% of adults in England and Wales suffering from a skin infection during their lifetime (Schofield et al., 2011). Worldwide, it is estimated that 1.9 billion people, which equates to one third of the world's population will suffer with a skin condition (Hay et al., 2015). The most common bacterial skin pathogens are *Staphylococcus aureus* and group A β -hemolytic streptococci; Herpes simplex is the most common viral skin disease and of the dermatophytic fungi, *Trichophyton rubrum* is the most prevalent cause of skin and nail infections (Aly, 1996). Normally, it is a single pathogen that causes issues with the skin, depending on the location of the infection with variation between the upper and lower body (Ki and Rotstein, 2008). Most primary skin infections usually occur in normal skin. However, secondary infections occur in skin that is already diseased, for example with intertrigo, due to the underlying disease the clinical picture and course of these infections vary (Aly, 1996). With primary skin infections, impetigo, folliculitis and boils are common and these are usually down to infections with common skin pathogens including *S. aureus*, β -hemolytic streptococci, and coryneform bacteria (Sukumaran and Senanayake, 2016). In most skin infections these organisms enter the body through a break in the skin or hair follicle (Ki and Rotstein, 2008), commonly due to a cut or insect bite for example as outlined in Fig. 1. Other entry points into the body have also been identified (Fig. 1).

There are some systemic infections that involve skin reactions and symptoms caused by a pathogen or toxin, for example measles, varicella, gonococemia, and staphylococcal scalded skin syndrome (Aly, 1996). Dermatophytic fungi have a strong affinity for keratin and therefore invade keratinized tissue of the nails, hair, and skin (Aly, 1996). Clinically most skin infections follow a similar pattern of disease and cause erythema, edema, and more localized redness and inflammation. Focal accumulations of pus or fluid (vesicles, bullae) may form. Alternatively, lesions may be observed with no obvious inflammation. Nail infections cause discoloration of the nail and thickening of the nail plate (Aly, 1996).

Fig. 1 Infection routes into the human body, including infectious agents, hosts and mode of transmission.

Bacterial skin infections

Primary infections

Impetigo

Impetigo is the most common skin infection and there are three forms of impetigo that are recognized on the basis of clinical, bacteriologic, and histologic results (Aly, 1996). Impetigo causes lesions that may contain group A β -hemolytic streptococci, *S. aureus*, or both, and controversy exists about which of these organisms is the primary pathogen (Pereira, 2014). The lesions have a thick, adherent, recurrent, dirty yellow crust with an erythematous margin (Pereira, 2014). This form of impetigo is the most common skin infection in children and is highly contagious and requires prompt treatment which tends to be antibiotics that can be taken either topically or orally.

In staphylococcal impetigo, the lesions are always caused by *S. aureus*, and are superficial, thin-walled, and bullous (Hartman-Adams et al., 2014). When a lesion ruptures, a thin, transparent crust appears which can be distinguished from the stuck-on crust of common impetigo. This distinctive appearance of bullous impetigo results from the local action of the epidermolytic toxin (exfoliation), the lesions are often found in clusters (Hartman-Adams et al., 2014).

Ecthyma is a deeper form of impetigo. Lesions usually occur on the legs and other areas of the body that are generally covered, and they often occur as a complication of debility and infestation. The ulcers have a punched-out appearance when the crust or purulent materials are removed, the lesions heal slowly and leave scars (Hartman-Adams et al., 2014). Treatment is dependent on the severity of the infection, but can include antibiotics.

Cellulitis

Streptococcus pyogenes is the most common agent of cellulitis (Stevens and Bryant, 2016). Which is inflammation of loose connective tissue, particularly subcutaneous tissue and most common to occur in legs (Stevens and Bryant, 2016). The pathogen generally invades through a breach in the skin surface, and infection and a tissue oedema occur (Stevens and Bryant, 2016). Cellulitis can happen in normal skin, but the lesion in cellulitis is erythematous, oedematous, brawny, and tender, with borders that are poorly defined (Stevens and Bryant, 2016).

No absolute distinction can be made between streptococcal cellulitis and erysipelas (Morris, 2008). Clinically, erysipelas is more superficial, with a sharp margin as opposed to the undefined border of cellulitis, lesions usually occur on the cheeks (Morris, 2008).

Staphylococcal scaled skin syndrome

Staphylococcal scalded skin syndrome, also known Lyell's disease or toxic epidermal necrolysis, starts as a localized lesion, followed by widespread erythema and exfoliation of the skin (Mishra et al., 2016). This disorder is caused by phage group II staphylococci which elaborate an epidermolytic toxin (Mishra et al., 2016). The disease is more common in infants than in adults (Mishra et al., 2016).

Folliculitis

Folliculitis can be divided into two major categories: superficial and deep. The most superficial form of skin infection is staphylococcal folliculitis, manifested by minute erythematous follicular pustules without involvement of the surrounding skin (Aly, 1996), with the scalp and extremities being favorite sites. Gram-negative folliculitis occurs mainly as a superinfection in acne vulgaris patients receiving long-term, systemic antibiotic therapy (Aly, 1996) with pustules are often clustered around the nose (Aly, 1996). *Cutibacterium acnes* (formerly *Propionibacterium acnes*) folliculitis is often misdiagnosed as staphylococcal folliculitis (Sun and Chang, 2017). The primary lesion is a white to yellow follicular pustule, Gram stain of pus reveals numerous intracellular and extracellular Gram-positive pleomorphic rods. The lesions are more common in men than in women (Sun and Chang, 2017). The process may start at the age when acne usually appears, yet most cases occur years later (Aly, 1996).

In deep folliculitis, infection extends deeply into the follicle, and the resulting perifolliculitis causes a more marked inflammatory response than that seen in superficial folliculitis (Aly, 1996). The primary lesion is a follicular pustule pierced by a hair. Bearded men tend to be more prone to this infection than shaven men (Aly, 1996).

Many people suffer from boils, these are due to a staphylococcal infection of a follicle with involvement of subcutaneous tissue (Lin et al., 2018). The preferred sites of boils are the hairy parts or areas that are exposed to friction (Aly, 1996).

Secondary infections

Secondary skin infections of pre-existing wounds, skin conditions, burns or retention cysts are common. Broken or damaged skin is prone to infection with bacteria, including *Staphylococcus* spp., *Streptococcus* spp. and *Corynebacteria*. These bacteria infect pre-existing skin conditions and can cause severe infections that need to be treated with antibiotics.

Intertrigo

Intertrigo is most commonly seen in overweight adults and children (Janniger et al., 2005). In the skin fold which is associated with obesity, heat, moisture, and rubbing produce erythema, maceration, or even erosions (Janniger et al., 2005). Overgrowth of resident or transient flora may produce this problem, and the bacteria involved can vary on a case by case basis (Janniger et al., 2005).

Viral skin diseases

Viral skin diseases covers a wide range of conditions, with the most common symptom being a rash (Ramdass et al., 2015). Most viral skin conditions are self-limiting, treatment would be given in severe cases, especially where sequela could occur.

Herpes simplex virus

Herpes simplex virus is a neurotropic pathogen, with clinical disorders ranging from harmless skin manifestations, such as oral or facial lesions to severe infections of the central nervous system (Duarte et al., 2019). The virus is acquired in childhood and produces infections throughout a person's life, due to the ability of the virus to infection and remain latent in neurons (Kramer et al., 2003). Worldwide approximately 60% of the population have antibodies against this virus, with 20–40% of those that are infected developing symptoms (Looker et al., 2015). Common symptoms of this virus including, itching and burning sensations before any blisters appear. One or more painful fluid filled blister can appear, these are most common on the lips, but can occur anywhere on the body and commonly referred to as cold sores. Blisters break open and form a crust before healing. Sores appear between 2 and 20 days after contact with an infected person and can last up to 10 days. Antiviral medications, such as acyclovir, famciclovir, and valacyclovir, are often given and are effective, they can help to reduce the severity and frequency of symptoms, but cannot cure the infection.

Chickenpox virus

Chickenpox, also called variella, is an extremely common virus which is common in children but can also infect adults, particularly if they did not have this virus in childhood (Gershon et al., 2015). It is a highly contagious infection that causes an itchy, spotty rash with blisters being able to occur anywhere on the body. Chickenpox is easily transmissible with infection happening by being in close contact with an infected individual for example, being in the same room as well as touching fomites that have been handled by an infected person (Fig. 1). Chickenpox, is self-limiting and symptoms usually last for 1-week, topical treatments can help to ease the symptoms (Gershon et al., 2015). Shingles, which tend to occur in older people, is caused by the same virus that causes chickenpox, when a person has chickenpox, the virus remains in the body, it can be reactivated later in life and cause shingles particularly if the immune system is lowered. You cannot pass shingles from person to person, but a person could get chickenpox if they have not had it previously. There is a vaccine for shingles, it commonly given to those aged 70 or over.

Fungal skin diseases

Several genera of fungi are responsible for skin diseases and are known as dermatophytes, but some yeasts which are not classed in this group can also cause skin infections.

Athletes foot

Athlete's foot (tinea pedis) is a fungal infection that usually begins between the toes. It commonly occurs in people whose feet have become very sweaty while confined within tightfitting shoes. A variety of fungi all belonging to a group called dermatophytes is responsible (Crawford, 2009). Signs and symptoms of athlete's foot include a scaly rash that usually causes itching, stinging and burning. Athlete's foot is contagious and can be spread via contaminated floors, towels or clothing (Crawford, 2009).

Athlete's foot is closely related to other fungal infections such as ringworm. It can be treated with over-the-counter antifungal medications, but the infection often recurs (Crawford, 2009). Keeping the area clean and dry limits re-infection.

Ring-worm

Ringworm of the body (tinea corporis) is a rash caused by a fungal infection. It's usually a red, itchy, circular rash with clearer skin in the middle. Ringworm gets its name because of its appearance. Ringworm is related to athlete's foot (tinea pedis) and ringworm of the scalp (tinea capitis; Leung et al., 2020). Ringworm often spreads by direct skin-to-skin contact with an infected person or animal. Mild ringworm often responds to antifungal medications that are applied to the skin. For more-severe infections, antifungal pills can be taken, usually for several weeks. Signs and symptoms of ringworm include a scaly ring-shaped area, particularly on the trunks arms or legs that can be itchy (Leung et al., 2020). Ringworm, is a zoonoses and so is transmitted between animals and humans and from human to human, it is highly infectious and easily transmissible (Leung et al., 2020).

Nail infections

Many infections of the nail and nail bed are caused by fungus, these are common problems and any nail of the hand or foot can become infected (Christenson et al., 2018). However, they are more common on toe nails (Christenson et al., 2018). Fungal nail infections are characterized by discolouration, thickening or distortion of the nail. The nails may also become brittle or crumbly and there is usually some pain and discomfort associated with infection. In addition, the area around the nail and nail bed can become itchy, swollen and red. Nail and nail bed infections are often associated with Athletes foot. Treatment is not always needed for mild infections, these are normally self-limiting and unlikely to cause further problems. For more severe infections, anti-fungal medication may be used.

Bacterial infections

Bacterial infections can be mild infections of the skin or of an internal organ, they can multiply rapidly within the body and can produce toxins (Aly, 1996), in more severe cases the result could be septicaemia. This occurs when a bacterial infection elsewhere in the body enters the bloodstream, it can quickly become life-threatening. There are many bacterial species that can result in infections.

Bacterial meningitis

Meningitis can be both viral and bacterial, viral is the most common and least serious type (Hussein and Shafran, 2000). Bacterial meningitis is rarer, but is more serious. Several different bacteria can cause meningitis including, meningococcal bacteria which is caused by *Neisseria meningitidis* and pneumococcal bacteria. For *Neisseria meningitidis*, disease-causing strains are classified according to the antigenic structure of their polysaccharide capsule. Serotype distribution varies markedly around the world. Among the 13 identified capsular types of *N. meningitidis*, six (A, B, C, W135, X, and Y) account for most disease cases worldwide (Rouphael and Stephens, 2012). Meningitis is an infection of the membranes surrounding the brain and spinal cord (Rouphael and Stephens, 2012), this can interfere with the blood flow which in turn could lead to paralysis or a stroke. It can be acute with a rapid onset of symptoms or it can be chronic, both forms require rapid treatment with antibiotics (Hussein and Shafran, 2000). Anyone can potentially get meningitis, but it's more common in babies and young children, teenagers and young adults, elderly people and people with a weakened immune system—for example, those with HIV and those having chemotherapy. There are numerous vaccines that can provide protection against the bacteria responsible.

Urinary tract infections

Urinary tract infections are very common infections that can affect the bladder, the kidneys or the tubes that connect them. The urinary tract becomes infected usually by bacteria, that come from the gut, they enter the urinary tract through the urethra (Flores-Mireles et al., 2015). Urinary tract infections (UTIs) are a severe public health problem and are caused by a range of pathogens, but most commonly by *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, *Enterococcus faecalis* and *Staphylococcus saprophyticus* (Flores-Mireles et al., 2015). They are more common in women than men, with some women experiencing them regularly. They are painful and uncomfortable with common symptoms including the need to urinate more often, pain or discomfort during urination, strong odor from the urine and blood in the urine. In elderly person, urinary tract infections are often associated with confusion (Flores-Mireles et al., 2015). They are easily treatable with antibiotics, with symptoms lasting for a 3–5 days following the commencement of treatment (Flores-Mireles et al., 2015). Reoccurring infections are common, some patients are more susceptible to these than others, they normally occur due to failure to eradicate the infection in the first place, a re-lapse or re-infection from the original source.

Respiratory tract infections

Respiratory tract infections can affect the sinuses, throat, airways and lungs, they can be caused by both viruses such as the common cold and bacteria. This section is going to focus on bacteria. The upper respiratory tract is considered to be the airway above the glottis and includes the nose, sinuses, pharynx and larynx (Mete and Akbudak, 2018). Typical infections in this section include tonsillitis and laryngitis. Tonsillitis is commonly caused by viral infection but up to 40% of cases can be attributed to a bacterial infection with group A *Streptococcus* spp. being responsible for the majority of cases (Georgalas et al., 2014). However, other bacteria including *Neisseria gonorrhoeae*, *Corynebacterium diphtheriae*, or *Haemophilus influenzae* may be the cause (Georgalas et al., 2014). Typically, the infection is spread between people through the air. Lower respiratory tract infections are more severe than upper respiratory infections, as these are infections of the trachea, bronchial tubes, bronchioles and lungs (Dasaraju and Liu, 1996). The two most common infections are bronchitis and pneumonia. Bronchitis is inflammation of the bronchi in the lungs. Symptoms include coughing up sputum, wheezing, shortness of breath, and chest pain. Bronchitis can be acute or chronic, with *Mycoplasma pneumoniae* or *Bordetella pertussis* being the bacteria responsible. Pneumonia is an inflammatory condition of the lung primarily affecting the small air sacs known as alveoli. Symptoms typically include dry cough, chest pain, fever and difficulty breathing. Pneumonia is usually caused by infection with bacteria, with *Streptococcus pneumoniae* isolated in nearly 50% of cases (Dion and Ashurst, 2020), with drug-resistant versions becoming more common, including drug-resistant *Streptococcus pneumoniae* (DRSP) and methicillin-resistant *Staphylococcus aureus* (MRSA). All respiratory tract infections that are attributed to a bacterial source can be treated with antibiotics.

Legionella

Legionella species are Gram-negative bacilli (Winn, 1996). Legionellosis is a collective term for diseases caused by legionella bacteria including the most serious Legionnaires' disease. This disease is a potentially fatal form of pneumonia and everyone is susceptible to infection (Winn, 1996). The risk increases with age but some people are at higher risk including those aged 45 or over, those that smoke or drink heavily and those that are suffering from pre-existing medical conditions including diabetes and heart disease (Winn, 1996). *Legionella pneumophila* and related bacteria are common in natural water sources such as rivers, lakes and reservoirs, but usually in low numbers. They may also be found in purpose-built water systems such as cooling towers, evaporative condensers, hot and cold-water systems and spa pools (Winn, 1996). Most infections can be treated with antibiotics.

Aspergillus

Aspergillus is a fungus. All members of the genus *Aspergillus* are members of the Ascomycota phyla. *Aspergillus* species are highly aerobic and are found in almost all oxygen-rich environments, where they commonly grow as molds on surfaces (Latgé and Chamilos, 2019). *Aspergillus* species are common contaminants of starchy foods (such as bread and potatoes), and grow in or on many plants and trees. *Aspergillus niger* can be found growing on damp walls, as a major component of mildew. Several species of *Aspergillus*, including *A. niger* and *A. fumigatus*, will readily colonize buildings, favoring warm and damp or humid areas such as bathrooms (Latgé and Chamilos, 2019). Aspergillosis is caused by breathing in small particles, called spores, of aspergillus in the air. Symptoms include, shortness of breath, cough or wheezing along with a high temperature. There are several different types of aspergillosis including allergic bronchopulmonary aspergillosis, chronic pulmonary aspergillosis and invasive pulmonary aspergillus (Latgé and Chamilos, 2019). Infections are treated with anti-fungal medication and possibly steroids.

Systemic infection

Systemic bacterial infection, commonly referred to as Sepsis is defined as an overwhelming innate inflammatory response to an infection, caused by bacteria entering the bloodstream (Singer et al., 2016). Sepsis is a very severe condition that can result in fatality if not treated promptly and can be caused by several bacterial species. The most common Gram-positive bacteria isolated in such sepsis cases are *S. aureus* and *Strep. pneumoniae*, and the most common Gram-negative bacteria are *E. coli*, *Klebsiella* spp. and *P. aeruginosa* (Ramachandran, 2014; Opota et al., 2015). Among those who are most vulnerable are the immunocompromised, including the elderly, new-born babies, and patients with previous or current trauma and conditions, such as diabetes and cancer (Lever and Mackenzie, 2007). Treatment is with antibiotics which are normally given intravenously due to the severity of this condition.

Foodborne illness

Foodborne illness, more commonly known as food poisoning, is the illness resulting from the consumption of contaminated food. This contamination can be viral, parasitic or due to toxins, but it is most likely to be bacterial. Two thirds of human foodborne illness worldwide can be attributed to bacteria as the causative agent, with a high burden in developing countries (Abebe et al., 2020). Most cases of foodborne illness can be attributed to the consumption of animal products. Meat, dairy products, and eggs are the main vehicles that people are exposed to zoonotic bacteria. *S. aureus*, *Salmonella* species, *Campylobacter* species, *L. monocytogenes*, and *E. coli* are the major zoonotic bacterial pathogens which are the causative agents of food-borne illness and death worldwide.

Table 1 Overview of infectious dose for common bacterial pathogens associated with foodborne illness.

Microorganism	Infectious dose, Colony forming units (cfu)	References
<i>Salmonella</i> spp.	10,000 cfu	Catford et al. (2017)
<i>Campylobacter jejuni</i>	<1000 cfu	Janssen et al. (2008)
<i>L. monocytogenes</i>	>100 cfu per g	Swaminathan and Garner-Smith (2007)
<i>E. coli</i> O157	<50 cfu	Griffin et al. (1994)

(Abebe et al., 2020). According to the World Health Organisation (WHO), an estimated 600 million—almost 1 in 10 people in the world—fall ill after eating contaminated food and 420,000 die every year, with the biggest burden (40% of infections) being in the under 5 age group (WHO, 2020). In the UK, the number of reported foodborne illness is recorded by Public Health England (PHE), to date in 2020 there have been 20,188 reports of *Campylobacter* spp., followed by 2002 reports of *Salmonella* spp. and 1735 of *Giardia* spp. (Food Standards Agency (FSA), 2020). The infectious dose in humans differ depending on the bacterial species responsible for the foodborne illness, these are summarized in Table 1.

Campylobacter species

Campylobacter spp. is the leading cause of bacterial foodborne illness worldwide, with the majority of cases being attributed to the consumption of poultry and poultry products (Wilson et al., 2010; Hermans et al., 2011; Levin, 2007; Williams et al., 2014). Despite poultry being the number one agent responsible for the majority of human cases of *Campylobacter* there have been reported cases associated with other animals including pigs, cows, sheep, companion animals and wild birds, although human infection from these sources remains low (Denis et al., 2008; Horrocks et al., 2009; Zweifel et al., 2004; Little et al., 2008; Oporto et al., 2007; Gilpin et al., 2008; Kwan et al., 2008; Inglis et al., 2004; Busato et al., 1999; Kemp et al., 2005; Brown et al., 2004; Andrzejewska et al., 2013; Meerburg et al., 2006). In addition to the above sources there have also been reported cases, particularly in the developing world from un-pasteurized milk and water (WHO, 2020). In the UK, in 2017 there were 56, 729 reported cases of *Campylobacter* spp. (Food Standards Agency (FSA), 2020) and it is thought that 82% of hospital admissions with a diagnosis of food poisoning can be attributed to a *Campylobacter* infection (Adak et al., 2002). In humans, the infectious dose is believed to be low, at around 500 cells in an adult male (Robinson, 1981) with an incubation period of up to 10 days, with most people exhibiting symptoms by day four. Symptoms include diarrhea, which may be bloody, particularly in children, acute abdominal pain and fever. Most infections are self-limiting and those who suffer an infection recover quickly after resting and maintenance of fluid levels; a fatal outcome is rare and would usually occur in the elderly or those already suffering from another serious illness (Skirrow and Blaser, 2002). Despite treatment with antibiotics being rare, resistance to clinically important antimicrobials including macrolides and fluoroquinolones has been reported (Humphrey et al., 2007). Approximately 1% of cases develop long-term sequelae, such as inflammatory bowel syndrome or reactive arthritis.

Salmonella

When the general public think of food poisoning they tend to think of *Salmonella* spp. this is due to the publicity received in the press, particularly in the 1980s in the UK, when an outbreak of *Salmonella* linked to eggs made headlines, this led to most UK laying hens, reared under the Lion Code, to be vaccinated against *Salmonella*. This control measure led to a reduction in the number of cases in the human population seen in the UK. Despite this intervention there are still reported cases of foodborne illness attributed to *Salmonella* spp. each year, although not surprisingly in the UK, hens eggs are rarely the cause providing they are from vaccinated flocks. Chicken, pork and dairy produce can contain *Salmonella*, in addition fruit and vegetables have been implicated in some outbreaks if they have been washed with contaminated water. In the UK, in 2016 there were 8630 reported cases of *Salmonella* (Food Standards Agency (FSA), 2020), significantly less than *Campylobacter*. The symptoms of *Salmonella* include diarrhea, stomach cramps, nausea, vomiting and fever (Eng et al., 2015), with these symptoms developing between 12 and 72 h post infection, with symptoms lasting up to 7 days (Eng et al., 2015). Medical intervention is not normally required unless symptoms are severe or prolonged.

Listeria

L. monocytogenes is the bacterium responsible for Listeriosis in humans. The bacteria are widely present in the environment and infection occurs after the consumption of foods, particularly raw, chilled or ready to eat foods, unpasteurised milk and dairy products such as soft cheeses and meat and meat products are the most common sources of infections (Buchanan et al., 2017). Infections are usually sporadic, but outbreaks can occur. People with listeriosis have been reported to develop symptoms between 1 and 70 days after consuming food contaminated with *Listeria*, and this prolonged time between exposure and onset of symptoms makes it difficult to get accurate dose information (Buchanan et al., 2017). Symptoms include fever and diarrhea, similar to other foodborne illnesses. However, *Listeria monocytogenes* infection can cause severe disease, for example septicemia in vulnerable groups,

including the elderly, pregnant women, unborn and new-born babies, and people with impaired immunity. In these groups, listeriosis can present as infection of the bloodstream or brain. Due to the severity of infection and high case fatality rate, listeriosis is an important public health concern. Compared to other foodborne pathogens, infections in humans are relatively rare. In 2018, 156 cases of listeriosis were reported in England and Wales (Food Standards Agency (FSA), 2020), with the greatest number of cases being reported in those over the age of 80. The most serious cases of listeriosis are treated with antibiotics, with ampicillin used on its own or conjunction with another antibiotic (most likely to be gentamicin) is the treatment of choice (Temple and Nahata, 2000). In vulnerable groups where the most serious infections can occur which can lead to septicemia, then intravenous antibiotics will be given, treatment can last up to 6 weeks.

Escherichia coli and *Clostridia*

E. coli has also been associated with foodborne outbreaks of infection. This bacterium lives in the intestine of most animals and humans and is considered to be part of the normal healthy gut flora. There are numerous types of *E. coli* strains, whilst most are harmless there are some for example *E. coli* 0157 which can be more serious. The more virulent strains can cause stomach cramps, diarrhea and fever. Most infections are self-limiting but the more serious cases require treatment with antibiotics. The number of infections in the human population attributed to *E. coli* is lower compared to the other food-borne pathogens, with 608 cases of *E. coli* 0157 being reported in England and Wales in 2018 (Food Standards Agency (FSA), 2020).

Whilst lower in numbers compared to other bacteria, clostridia is also associated with foodborne illness. There are 2 species commonly implicated *C. perfringens* and *C. botulinum*. These are spore-forming bacteria, found in many environmental sources as well as in the intestines of animals and humans. *C. perfringens* is commonly found on raw meat and poultry. It prefers to grow in conditions with very little or no oxygen, and under ideal conditions can multiply very rapidly. Some strains of *C. perfringens* produce a toxin in the intestine that causes illness (Uzal et al., 2014). The symptoms include diarrhea and abdominal cramps, with the onset of symptoms being rapid (within 24 h) of ingesting the bacteria (Kiu and Hall, 2018), there can be a rapid onset of symptoms with most infections clearing within 24 h.

Norovirus

More commonly known as the winter vomiting bug, this is a highly contagious infectious bacterium and can easily spread from person to person (Robilotti et al., 2015) and so outbreaks are common in hospitals, schools and care homes. The symptoms include fever, diarrhea, nausea, vomiting and fever (Robilotti et al., 2015). Most cases are self-limiting and do not require treatment. The UK Food standards agency, estimated that 380,000 cases of norovirus linked to food occur annually in the UK (Food Standards Agency (FSA), 2020).

Conclusion

Microbial infection is a broad topic that covers infections caused by bacteria, viruses and fungi. There are several species within each microbe that are responsible for infections all over the body. Some infections can be self-limiting and will clear up without any medical intervention. However, other require medical treatment and in the case of bacterial infections this is antibiotics. Some infections can lead to serious post infection complications that can persist throughout a persons' life and so with this in mind any infection cannot be regarded as trivial. Whilst, a lot of research has been carried out in infection diseases there are still many unknowns but with the advancements in technology and whole genome sequencing these unknowns are reducing.

Glossary

Acid-fast staining A staining method used on acid-fast bacteria such as Mycobacteria, involves using a stain such as basic fuchsin and then decoloring with acid alcohol, which acid-fast bacteria resist.

Biofilm A structured community of bacterial cells enclosed in a self-produced polymeric matrix and adherent to an inert or living surface.

Capsule A dense polysaccharide or protein matrix surrounding the bacterial cell surface.

Cell wall associated proteins (CWAs) Surface proteins, that are covalently bound to the cell wall peptidoglycan, responsible for adhesion and colonization of host cells, and evasion of host immune responses.

Chemotaxis Movement towards or away from a chemical or stimuli.

Commensal bacteria Bacteria that are part of the normal human flora/microbiota.

Conjugation Transfer of genes from one bacterium to another by direct cell-to-cell contact or by a bridge-like connection between two cells called a pilus.

Copy number The number of copies of a plasmid found within a single bacteria cell.

Cytoplasm Fluid filled inner most area of the bacteria cell contained within the cytoplasmic membrane and contains the bacterial chromosome, mRNAs, ribosomes, proteins and metabolites required for growth and survival.

Cytoplasmic membrane Semi-permeable lipid bilayer that separates the inside of the cell (cytoplasm) from the surrounding environment.

Eukaryotic Cell has a membrane-bound nucleus and various other organelles such as mitochondria and Golgi body.

Fimbriae (singular fimbria) Small hair-like filamentous protein structures on the bacteria cell wall, numerous in number and have a role in adhesion to surfaces including host cells.

Flagella A long, thin appendage composed of flagellin, that is responsible for bacterial motility.

Gram staining A differential staining technique where bacterial cells either stain pink-red (Gram-negative) or purple (Gram-positive) depending on their cell wall structure.

Gram-negative bacteria Cell wall composed of a thin peptidoglycan layer and an outer lipid membrane. In a Gram stain, they do not retain crystal violet so stain red.

Gram-positive bacteria Cell wall composed of a thick peptidoglycan layer and no outer lipid membrane. In a Gram stain, they retain the crystal violet color and stain purple.

Human flora/Microbiota All the microorganisms (bacteria, fungi and protozoans) that live on or in humans.

Inclusion body Aggregates of stable substances, usually proteins found in the cytoplasm, and function as energy stores or carbon reservoirs.

Lipopolysaccharide (LPS) An endotoxin and powerful inflammatory stimulant that forms the major part of the outer

membrane in Gram-negative bacteria, composed of lipid A, core polysaccharide chain, and O-specific polysaccharide/O antigen.

Lipoteichoic acid (LTA) A macroamphiphile with a glycolipid anchored covalently to the cytoplasmic membrane.

M protein Protein that alters surface of cell wall and inhibits phagocytosis.

Messenger RNA (mRNA) A single-stranded RNA molecule that is complementary to one of the DNA strands of a gene, contains the genetic information to encode proteins.

Nucleoid Area within the cytoplasm that contains the bacterial DNA/chromosome.

Opportunistic bacteria Bacteria that are part of the normal human flora/microbiota but under certain circumstances such as weakened immunity or altered microbiota can cause infections.

Opsonin A receptor such as immunoglobulin G (IgG) or complement molecule used by neutrophils, macrophages, dendritic cells, and B lymphocytes to bind bacteria and initiate phagocytosis.

Opsonophagocytosis Phagocytosis initiated by an opsonin.

Outer membrane proteins (OMP)/Porins Transmembrane proteins that function as channels for the movement of solutes in and out of the cell.

Outer membrane Found external to the peptidoglycan layer in Gram-negative bacteria, consists of an inner layer composed of mainly phospholipids and an outer layer composed of lipopolysaccharide.

Pathogen-associated molecular pattern (PAMP) A macromolecule on the inside or outside of the bacteria cell wall that serve as a marker by which phagocytes can identify the pathogenic bacteria/microbes.

Pathogenic bacteria Bacteria that cause infections in healthy persons and are not part of the normal human flora/microbiota.

Peptidoglycan (PG) Main structural component of cell wall composed of alternating repeats of *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM) in adjacent layers that are cross-linked by short peptides.

Periplasmic space/periplasm A gel-like space between the inner peptidoglycan layer and outer membrane of Gram-negative bacteria.

Phagocyte pattern recognizing receptors (PRR) Soluble or membrane-bound proteins on the surface of phagocytes that recognize and bind to PAMPs. The interaction of a PAMP and PRR activates the phagocyte to ingest and destroy the bacteria.

Phagocytosis A process by which an immune cell ingests/engulfs a particle such as a bacterial cell and digests it.

Pili (singular pilus) Small hair-like filamentous protein structure that extends from cell wall, and depending on type involved in adhesion, genetic exchange, or twitching motility.

Plasmid An extrachromosomal self-replicating genetic element that are expendable as they are not part of the bacteria's permanent chromosome but carry genetic information that can provide a selective advantage such as antibiotic resistance.

Prokaryotic Cell lacking membrane-bound nucleus and other organelles.

Ribosomal RNA (rRNA) An RNA molecule that makes up part of the ribosome, some actively participate in protein synthesis.

Ribosome Site of protein synthesis.

Slime layer Similar to a capsule but less structured.

Teichoic acid (TA) Major component of Gram-positive bacteria cell wall, composed of wall teichoic acids and lipoteichoic acids.

Transcription Synthesis of an RNA molecule complementary to one of the two strands of the DNA.

Transduction Transfer of genes from one bacterium to another by a virus/phage.

Transformation Transfer of genetic information by free DNA from one bacterium to another.

Translation Synthesis of a protein by a ribosome using information provided by mRNA.

Twitching motility A flagella-independent form of bacterial motility by Type IV pili. The bacteria move due to the extension and retraction of the Type IV pili so cell is dragged across a surface in a gliding-like motion.

Type III secretion systems Commonly used by pathogenic Gram-negative bacteria to inject toxic proteins directly into eukaryotic host cells.

Type IV pili/secretion system Pilus extends through the outer membrane of the bacteria and can aid the bacteria in twitching motility or transfer of DNA to other cells via conjugation.

Virulence factor Molecules produced by the bacteria that help them cause infections, invade the host and evade host defences.

Wall teichoic acid (WTA) Composed of glycerol or ribitol residues containing phosphodiester links and attached to *N*-acetylmuramic acid of the peptidoglycan.

Introduction

Microorganisms are the smallest organisms on earth, and comprise of bacteria, archaea, fungi, protozoa, and viruses. Except for viruses, microorganisms are living single cell or a cluster of cells and are found in both aquatic and terrestrial environment (Beveridge, 1980; Madigan et al., 2019). The microbial cell has many shared features (Fig. 1), but the differences seen between

Fig. 1 Diagram of the major features of Prokaryote and Eukaryote cells. From Murray PR, Rosenthal KS and Pfaller MA (2015) *Medical Microbiology*. Philadelphia: Elsevier, pp. 107.

their internal cell structure is used to differentiate bacteria from fungi and protozoa (Beveridge, 1980; Madigan et al., 2019). Bacteria and archaea are defined as prokaryotic cells as they lack a nucleus and other membrane-bound organelles and their DNA is a single circular molecule, whereas fungi and protozoa are eukaryotes as they have a nucleus and an assortment of membrane bound organelles (Fig. 1; (Murray et al., 2015)). This chapter will focus solely on bacteria and aims to provide a basic understanding of the bacterial cell structure and organization and how it influences their ability to cause human infection and diseases.

Bacteria are a very large diverse group of microorganisms that are classified according to their morphology (size and shape), cell wall structure, and their metabolic and genetic features (which are discussed in other chapters). Most bacteria are defined as rod (bacillus), spherical (coccus) or spiral (spirillum) in shape (Fig. 2; Murray et al., 2015). Coccus-shaped bacteria are seen as single cells, pairs, long chains or clusters, whereas rod-shaped bacteria are simply cells that are longer in one dimension than the other, resulting in fat, thin, short or long rods. Spirillum-shaped bacteria are curved rods. However other bacteria groups are recognized by the unusual shape of their individual cells (Fig. 2), such as spirochetes, which are tightly coiled bacteria; filamentous bacteria, that form long thin cells or chains of cells; and budding or appendaged bacteria, that have long tubes or stalks as extensions of their cells. Bacteria vary in size from about 0.2 μm to more than 700 μm in diameter. Most rod-shaped bacteria are between 0.5 μm and 4 μm wide and less than 15 μm long, while coccus-shaped bacteria have an average diameter of about 0.5–1.0 μm (Murray et al., 2015). The size of bacteria is limited by their volume and ability to transport compounds in and out of the cell. A bacterial cell less than 0.1 μm in diameter has too small a volume to house the cells' essential components i.e., nucleic acids, proteins and ribosomes. Whereas if the bacteria cell is too large it cannot transport enough nutrients into the cell, as surface to relative to cell volume is too small. Hence, a significant advantage to being small is that the cell has a larger surface-to volume ratio so able to transport more nutrients into the cell, resulting in faster growth rates and larger populations. The surface-to volume ratio therefore also influences the ability of bacteria to adapt and evolve to changing environmental conditions (Madigan et al., 2019; Murray et al., 2015).

Fig. 2 Bacterial cell morphologies.

Most bacteria are harmless to humans and some are even useful and used in the food, drug, agriculture and energy industries. Some of these harmless bacteria have developed a symbiotic relationship with humans and are deemed part of the normal human flora or microbiota, also referred to as commensal bacteria. These bacteria are found on the human skin, and in the oral cavity, gastrointestinal (GI), respiratory and urogenital tracts, and contribute to human health and well-being by producing beneficial products and inhibiting the growth of harmful bacteria (Beveridge, 1980; Wilson et al., 2002). In return, the bacteria have access to nutrients. Harmful bacteria can cause infections and are defined as opportunistic or pathogenic bacteria. The severity of the infection depends on the molecules the infecting bacteria have on the cell surface and secrete into the surrounding environment, also termed virulence factors (Wilson et al., 2002). However, regardless of bacteria's morphology or whether they are harmless or not, the one thing they all have in common is a similar basic cell structure.

Bacterial cell structure

The bacterial cell can be split into three parts, the cytoplasm, cell envelope and external cell surface structures as shown in Fig. 3. Certain features are found in all bacterial cells, while others are specific to the bacterial species. This chapter will look at some of these features and how they may influence the ability of the bacteria to cause infections.

Cytoplasm

The inner most part of the bacterial cell is the cytoplasm where functions for cell growth, metabolism and replication are carried out. It is a predominately aqueous environment containing a nucleoid, ribosomes, inclusion bodies and plasmids. However, with the advancement in imaging and fluorescent proteins, different macromolecules within the cytoplasm including proteins, RNAs, DNA and lipids have been found to be organized and display complex subcellular localization patterns and are homologous to the eukaryotic cytoskeleton components actin, tubulin and intermediate filament protein (Ingerson-Mahar and Gitai, 2012). These cytoskeletal structures undergo dynamic reorganization and self-assembly, and are essential for processes ranging from cell division to differentiation, and localization of biochemical reactions for distributing metabolites (Govindarajan and Amster-Choder, 2016).

Fig. 3 Bacterial cell structures. From Murray PR, Rosenthal KS and Pfaller MA (2015) *Medical Microbiology*. Philadelphia: Elsevier, pp. 107.

Detailed information on the bacterial cytoskeleton which is beyond the scope of this chapter can be found in various open access reviews (Shih and Rothfield, 2006; Ingerson-Mahar and Gitai, 2012; Cho, 2015; Govindarajan and Amster-Choder, 2016).

Nucleoid

The nucleoid is a chromatin-dense area within the cytoplasm and contains the bacterial DNA, associated proteins and RNA that are responsible for controlling the bacteria's activity and reproduction (Fig. 3). As bacteria are haploid organisms, they have one chromosome that carries all the genes and genetic information it requires to survive as a living organism. The bacterial chromosome is a long circular molecule of double-stranded DNA, that is tightly looped and coiled into a supercoiled state and is not membrane bound (Thanbichler et al., 2005; Barer, 2018). The absence of a nuclear membrane means that when bacterial genes are transcribed the messenger RNA can be immediately transcribed and translated into protein, and that signals that influence bacterial transcription factors can do so directly on entering the cytoplasm (Dorman, 2013). The nucleoid is associated with several nucleoid-associated proteins (NAPs) that were formerly known as 'histone-like' proteins. NAPs are abundant within the chromatin as they bind to the chromosome DNA. Specifically, they have an important role in chromosome condensation and organization during DNA replication, and they also influence gene expression at the transcription level replication (Thanbichler et al., 2005; Dorman, 2013).

Plasmids

Many bacteria contain other naturally occurring genetic elements within the cytoplasm called plasmids (Fig. 3). Plasmids are small circular double stranded DNA that are distinct from the bacteria's chromosomal DNA; linear plasmids have also been found in a variety of bacteria such as *Borrelia* (cause of Lyme disease) and *Streptomyces* (largest antibiotic-producing genus) (Clark et al., 2019). They are supercoiled DNA molecules that vary in size from approximately few hundred to over a million base pairs (Barer, 2018). Plasmids are autonomous self-replicating molecules that are expendable as they rarely contain genes required for growth, but they often carry genes that provide the bacteria cell with a selective advantage such as antibiotic resistance. As mobile elements, some plasmids encode all the genetic information required to transfer from one bacterial cell to another via conjugation, while others can be transferred into the cell by transformation or transduction. There are two mechanisms that plasmids can use to spread, first is by direct transfer from one bacterium to another in a specific microenvironment, and secondly by being carried in a host to another such as in a hospital (Barer, 2018).

Bacteria may possess different plasmids in different numbers, this is called copy number, so may possess as few as one in the case of large plasmids or several hundred for smaller ones (Novick, 2002). The copy number influences the effect of plasmid related phenotypes such resistance to antibiotics, because more copies of the plasmid will mean more antibiotic genes resulting in increased antibiotic resistance (Murray et al., 2015). With the advent of genomic sequencing, plasmid DNA is also being sequenced, thus plasmids can now be typed according to their genetic features (Barer, 2018). Pathogenic bacteria are known to possess plasmids that carry genes for various virulence factors enabling them to successfully colonize hosts and cause infections (Thomas and Summers, 2008). In some cases plasmids can integrate into the bacterial chromosome, which results in the transfer of plasmid DNA/genomes into the bacteria's genome (Clark et al., 2019). Certain plasmids can also mediate the transfer of host chromosomal genes from one bacterial cell to another (Novick, 2002), and this is the basis of genetic engineering (which will not be discussed in this chapter).

Ribosomes

Ribosomes serve as the site of messenger RNA (mRNA), translation and protein synthesis in bacteria (Fig. 3). Bacterial ribosomes are composed of 30S and 50S subunits resulting in a sedimentation coefficient of 70S (Barer, 2018). Each ribosomal subunit comprises of specific ribosomal RNA (rRNA) and proteins. The 30S subunit comprises of 16S rRNA and 21 proteins, while 50S comprises of 5S and 23S rRNA, and 31 proteins (Madigan et al., 2019). The 16S, 23S and 5S rRNA are transcribed together with some tRNAs to give a single pre-rRNA (Clark et al., 2019). The rRNA then form part of the ribosome mechanism that translates the mRNA. Thus transcription and translation are coupled during protein synthesis, meaning the mRNA is read before the mRNA has been completed and released from the transcription complex, allowing the bacteria to grow and reproduce quickly (Grogan, 2011). Bacterial ribosomes and proteins are also very different to eukaryotic ribosomes making them a major target for antimicrobial compounds (Murray et al., 2015).

Inclusion bodies

Under certain growth conditions, inclusion bodies are produced in the cytoplasm of some bacteria and function as energy stores or carbon reservoirs (Fig. 3). They can often be seen without staining under a light microscope and are usually enclosed by a non-unit membrane protein layer, while others are defined as non-membrane (Hobot, 2015). Inclusion bodies are normally seen as dense, large spherical or cylindrical particles or aggregations, ranging from 0.2 μm to 1.2 μm , and composed of 80–95% of the heterologous expressed protein (Ramon et al., 2014). They may also contain other proteins such as heat shock proteins (e.g., IbpA), chaperons (e.g., DnaK system), phospholipids from membranes and nucleic acids (Ramon et al., 2014). Storing carbons such as glycogen, lipids such as poly- β -hydroxybutyric acid, inorganic phosphate in the form of polyphosphate and other substances in an insoluble form can be advantageous to the bacteria as it reduces osmotic stress and is a major energy storage mechanism for future use (Madigan et al., 2019). In recent years, inclusion bodies have been deemed as undesirable by-products in recombinant protein production, while their ability to form aggregates has been utilized as a model to understand protein aggregation in human diseases such as Huntington disease and Alzheimers (Ramon et al., 2014).

Cell envelope

Cytoplasmic membrane

The cytoplasmic membrane is the innermost layer of the cell envelope and surrounds the cytoplasm, vitally separating it from the environment (Fig. 3). It is structurally weak giving little protection from osmotic lysis hence, if the cytoplasmic membrane is damaged or compromised the cell's integrity is destroyed and the cytoplasm leaks into the environment leading to cell death. However, the cytoplasmic membrane structure is a semipermeable barrier perfect for the movement of solutes in and out of the cell.

The cytoplasmic membrane comprises of a phospholipid bilayer similar to eukaryotic cells but without the sterols/cholesterol (Murray et al., 2015). The bacterial phospholipid bilayer is made up of two hydrophobic fatty acid tails that point inward towards each other with hydrophilic glycerophosphate heads pointing out into the environment or cytoplasm (Fig. 4). The phospholipid bilayer's oily nature gives flexibility and fluidity to the membrane making it a semifluid environment (Madigan et al., 2019). The cytoplasmic membrane also has a high protein content and contribute to the mechanical structure of the membrane (Barer, 2018). Integral membrane proteins are firmly embedded in the membrane bridging the whole membrane, while peripheral membrane proteins have one end anchored in the membrane with the other end pointing in or out of the cell (Fig. 4). Some peripheral membrane proteins are lipoproteins as they have a lipid tail that anchors them to the cytoplasmic membrane. Peripheral and

Fig. 4 Structure of cytoplasmic membrane. In—faces the cytoplasm; Out—faces the environment.

Fig. 5 Membrane-spanning transport systems. (A) Carrier protein systems; (B) Classes of transport systems.

integral membrane proteins interact for important cellular processes such as energy metabolism and transport (Grogan, 2011; Madigan et al., 2019). Such proteins usually cluster together so they remain close to each other in the semifluid environment of the cytoplasmic membrane.

One of the cytoplasmic membrane's functions is as a selective permeable barrier that regulates the movement of substances in and out of the cell and maintaining and regulating the bacterial cell's internal ionic concentration and osmotic pressures (Hobot, 2015). The hydrophobic component of the membrane acts as a tight barrier allowing the passive diffusion of water and some small hydrophobic molecules but not the passage of larger or charged molecules, which have to be transported through the membrane via transport proteins, also known as transport systems or permeases (Hobot, 2015; Madigan et al., 2019). Transport proteins generally span the membrane to form a channel, and it is through this channel that they mediate the passage of substances by one of three types of transport processes catalyzed by a protein called porter (Fig. 5).

Uniporters carry the substance across the membrane unidirectionally, Symporters or cotransporters transport two substances across the membrane at the same time, typically the substance and a proton, while Antiporters transport one substance into the cell and simultaneously transport a second substance out of the cell (Madigan et al., 2019). Transport proteins operate by one of three transport mechanisms (Fig. 5B), all of which require energy from ATP, proton motive force or some other energy-rich organic compound (Grogan, 2011). The simple transport mechanism (Fig. 5B) consists only of a membrane spanning transport protein that is driven by the proton motive force. Essentially the mechanism exploits the principle that a proton gradient can be used as an energy source by a symporter transport protein to move the substance across the membrane (Grogan, 2011). A well understood example is the transportation of lactose into *Escherichia coli* by the simple transport protein, lactose permease (Deutscher et al., 2006). Group translocation involves modifying the chemical structure of the substance as it is transported across the membrane and is driven by an energy-rich organic compound rather than proton motive force or ATP (Fig. 5B). One of the best studied examples is the phosphotransferase system, used to transport sugars such as glucose across the membrane of *E. coli* (Saier Jr, 2015). The system is driven by phosphoenolpyruvate, an energy-rich intermediate of glycolysis and involves the phosphorylation of the sugar as it passes through the membrane. The third mechanism is the ABC transporter that consists of three proteins, one of which hydrolyzes ATP for energy (Fig. 5B). This transport mechanism utilizes proteins bound to the external surface of the cytoplasmic membrane or periplasmic binding proteins along with the transporter proteins and ATP to move sugars, amino acids, inorganic nutrients such as sulfate and phosphate and some metals across the cytoplasmic membrane (Madigan et al., 2019).

The bacterial cytoplasmic membrane not only acts as a permeability barrier, but also carries out many of the functions carried out by the organelles in eukaryotic cells, therefore it is a major site for electron transport and energy production (Hobot, 2015). One important energy source associated with the membrane is the proton motive force. Since the membrane can have positively charged protons (H^+) on the outside of the membrane with hydroxyl ions (OH^-) on the inside, a charged energized state is created which can drive many energy-requiring functions such as transport proteins, motility and biosynthesis of ATP (Madigan et al., 2019). The cytoplasmic membrane also contains proteins and enzymes involved in cell wall synthesis including membrane synthesis and septum formation during replication, detecting the concentration of molecules in the surrounding environment, and translocating signals to genetic and metabolic processes in the cytoplasm (Salton et al., 1996; Wilson et al., 2002).

Cell wall

On the outside of the cytoplasmic membrane and covering the whole cell is the cell wall (Fig. 3). The cell wall's main functions are to maintain the mechanical strength and shape of the bacterial cell while protecting it from the internal osmotic pressure found in the cytoplasm, as its integrity is critical to the cell's viability (Scheffers and Pinho, 2005). Thus, if the cell wall is damaged, the cytoplasmic content will be released into the surrounding environment resulting in cell death (cell lysis (Hobot, 2015)). The cell wall is composed of a rigid layer of peptidoglycan (PG), also known as murein (Weidel and Pelzer, 1964). PG is a heteropolymer that consists of long glycan chains of alternating *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM) sugars that are cross-linked by short peptides of D- and L-amino acids (Fig. 6A) (Coleman and Smith, 2014). The chemistry of the glycan chain only differs slightly between bacteria, while the peptide cross-links vary considerably and are responsible for giving the peptidoglycan structure the flexibility needed to allow the bacteria to alter its shape and cell wall mechanical properties during growth and differentiation (Knox and Wicken, 1973; Scheffers and Pinho, 2005). Differences in the structure of the PG are used to differentiate between Gram-positive and Gram-negative bacteria and will be discussed in detail below. The PG can be destroyed by enzymes such as lysozyme found in tears, saliva and other bodily fluids, and is a defence mechanism used by other bacteria, leading to the lysis of the cell wall (Vollmer, 2015). It is also a target for various antibiotics such as β -lactams (penicillin, cephalosporin) and glycopeptides (vancomycin), as they inhibit peptidoglycan formation (Coleman and Smith, 2014).

Gram-positive bacteria

Gram-positive bacteria have a thick PG layer approximately 10–20 layers thick that retains the crystal violet stain in a Gram stain giving the bacteria a purple color (Fig. 6C; Scheffers and Pinho, 2005). Most Gram-positive bacteria cell walls are also composed of teichoic acids (TAs) or related glycopolymers, capsular polysaccharides and cell wall associated proteins, and collectively they make up a polyanionic mesh-like matrix that surrounds the cytoplasmic membrane giving the Gram-positive bacteria cell wall elasticity, porosity and tensile strength (Xia et al., 2010; Neuhaus and Baddiley, 2003). TAs are composed of wall teichoic acids (WTA) and lipoteichoic acids (LTA). WTAs are water-soluble anionic polymers of glycerol phosphate or ribitol phosphate linked by phosphodiester bonds covalently bound to MurNAc residues and known WTA structures have a great diversity between bacterial species and even between clonal groups. While LTAs are a macroamphiphile with a glycolipid anchored covalently to the cytoplasmic membrane (Neuhaus and Baddiley, 2003). Together WTAs and LTAs may contribute to the net negative charge of Gram-positive bacteria cell walls (Xia et al., 2010), but their overall function remains unclear, although it has been suggested that they have a role in adhesion, cell wall maintenance, and host-mediated immune responses (Neuhaus and Baddiley, 2003; Xia et al., 2010).

Gram-negative bacteria

Gram-negative bacteria have a more complex multi-layered cell wall that stains pink-red in a Gram stain. The Gram-negative cell wall consists of a thin PG layer next to the cytoplasmic membrane and an outer membrane external to the PG (Fig. 6D) (Bower and Rosenthal, 2006). In-between the PG and outer membrane is the periplasm or periplasmic space. Within this 10–25 nm gel-like space are proteins that facilitate the transport of molecules in and out of the cell, and hydrolytic enzymes such as proteases, phosphatases and lipases involved in metabolism (Graham et al., 1991; Bower and Rosenthal, 2006; Murray et al., 2015). The outer membrane consists of an inner layer composed of mainly phospholipids and an outer layer composed of lipopolysaccharide (LPS, Fig. 6C) (Bower and Rosenthal, 2006). LPS is composed of three parts: lipid A, core polysaccharide chain, and O-specific polysaccharide or O antigen (Bower and Rosenthal, 2006). Lipid A is a hydrophilic region composed of fatty acids attached to a disaccharide backbone and is a strong stimulator of the human innate and immune responses. Lipid A as an endotoxin will be discussed in more detail later in the chapter. The core region is a branched polysaccharide of 9–12 sugars, including negatively charged 2-keto-3-deoxy-ocanate, and is phosphorylated (Hancock, 1997). Together with lipid A the core region is an essential part of the LPS structure and bacteria viability, as divalent cations bridge the phosphates on lipid A and the core region to give the outer membrane strength (Murray et al., 2015). The O antigen region is attached to the core region and consists of 50 to 100 repeating units of 3–7 sugars that extend away from the bacteria. Differences in this region are used clinically to distinguish different bacterial strains by their O antigen serotype, for example, *E. coli* O157:H7 (O antigen: flagellin) serotype for the enterohemorrhagic *E. coli* (Bower and Rosenthal, 2006).

Importantly the outer membrane maintains the bacteria structure but also functions as a selective permeability barrier (Hancock, 1997). To aid with the transport of small molecules through the membrane are proteins called outer membrane proteins (OMP) or porins (Fig. 6C). Porins are made of three subunits that traverse the outer membrane to form a 1 nm in diameter channel that allows the passage of small and hydrophilic molecules but restricts access to larger and hydrophobic molecules such as bile salts, toxins, lysozyme, and many antibiotics (Bower and Rosenthal, 2006). The outer membrane also contains secretion systems that traverse the membrane to allow for the secretion of molecules such as toxins hydrolytic enzymes and other proteins out of the bacterial cell. To date there are 6 known secretion systems called type I to VI, which either secrete the molecule directly out of the cell in a single process (Type I, III, IV and VI) or move it into the periplasm to await transport across the outer membrane (Type II and V; Dalbey and Kuhn, 2012; Madigan et al., 2019). Type III and IV secretion systems are discussed in detail later in this chapter.

Acid-fast bacteria—Mycobacterium

Mycobacteria are Gram-positive bacteria but their cell wall is composed of a thick PG layer covered by covalently bound arabinogalactan (AG) polysaccharides and mycolic acids (2-alkyl-3-hydroxy fatty acids), and a variety of glycolipids, sulfolipids, and glycerophospholipids (Coleman and Smith, 2014). The high lipid content gives the cell wall a wax-like coat that is very hydrophobic in nature resulting in such bacteria being resistant to Gram staining, therefore they are stained using an acid-fast test such as Ziehl-Neelsen, and hence being called acid-fast bacteria (Murray et al., 2015). The complex nature of the acid-fast cell wall also makes it more resistant to antibiotics as they are unable to penetrate the cell and has anti-phagocytic properties. To facilitate the uptake of nutrients the cell wall layer also contains porin proteins (Coleman and Smith, 2014).

Cell surface structures and components

Bacteria also have structures or components on the outside of their cell wall that are in contact with the environment, many of which are classed as virulence factors (Fig. 3). The structures described in detail below are important in the survival of the bacteria, and in clinically relevant bacteria help initiate infections.

Capsules and slime layers

Many bacteria produce a capsule or slime layer on their cell surface. These terms are often used interchangeable, but they are actual two different structures, neither of which confer any structural strength to the bacteria cell or are required for growth (Roberts, 1996). A capsule also known as a capsular polysaccharide is a dense, hydrated, tightly organized layer of complex polysaccharide that covalently adheres to the bacteria cell wall phospholipid or lipid-A molecules (Fig. 7A; Roberts, 1996). Not all capsules are polysaccharide based, some Bacilli have simple polypeptide capsules. In comparison, a slime layer is a diffuse layer, composed of extracellular polysaccharide (EPS) molecules that are of loosely bound to the cell wall so can easily be lost from the cell wall (Fig. 7B; Roberts, 1996).

Capsular polysaccharides are composed of over 95% water and repeating monosaccharides coupled by glycosidic linkages. The composition of capsules is very diverse, and is species and strain dependent (Corbett and Roberts, 2008). In human pathogens such as *E. coli*, *Streptococcus pneumoniae*, Group A *Streptococci*, *Klebsiella pneumoniae* and *Staphylococcus aureus*, a large number of different capsule serotypes have been identified (O’Riordan and Lee, 2004; Roberts, 1996) and this knowledge is often used to type these bacteria. For example, *E. coli* has over 80 different capsular polysaccharides designated K antigens or a polymer derived from 170 different O antigens (Schembri et al., 2004). Certain serotype K1 and certain types of O antigens are associated with specific infections, such as K1 capsule with neonatal meningitis and urinary tract infection (UTI), and K5 capsule with UTI and sepsis (Schembri et al., 2004). Thus, capsular polysaccharides are often used as a typing tool in the diagnosis and identification of clinical bacteria (Table 1).

In pathogenic bacteria capsular polysaccharides and EPS are classed a key virulence factors, as they have a role in colonization and are involved in microbe-host interactions due to their antigenic properties (Table 2) (Roberts, 1996; O’Riordan and Lee, 2004; Schembri et al., 2004). Bacteria with a capsular polysaccharide are known to have an enhanced ability to adhere and colonize epithelial and endothelial cells, and mucosal surfaces compared to unencapsulated bacteria (Wen and Zhang, 2015). The primary role of the bacterial capsule is to protect the bacteria from the host innate and adaptive immune systems. Capsular polysaccharide expression has been shown to confer resistance to complement-mediated killing in the absence of a specific antibody as the capsule

Table 2 Capsular polysaccharide virulence associated functions.

Function	Virulence role
Prevention of desiccation	Transmission and survival
Adherence	Colonization of oral surfaces Colonization of indwelling catheters
Resistance to nonspecific host immunity	Complement-mediated phagocytosis Complement-mediated killing
Resistance to specific host immunity	Poor antibody response to the capsule

acts as a permeable barrier to complement factors, so the underlying bacteria cell surface structures that would have been potent activators of the alternative pathway are masked (Roberts, 1996). The capsule may also confer resistance to complement-mediated opsonophagocytosis by polymorphonuclear leukocytes (PMNL) (Corbett and Roberts, 2008; Wen and Zhang, 2015). Evidence also suggests that certain capsular polysaccharides may affect cytokine release by host's cells, thus disrupting the immune response cascade (Roberts, 1996). While most capsular polysaccharides can trigger an immune response, a small set of capsular polysaccharides such as *E. coli* serotype K1 are poorly immunogenic, thus the infected person mounts a poor antibody response to the bacteria while the capsule gives the bacteria some form of resistance against host's specific immune responses (Roberts, 1996).

The EPS in bacteria such as *Staphylococcus epidermidis*, *Streptococci* and *Pseudomonas aeruginosa*, is associated with biofilm formation. Biofilms are a thick layer of bacteria bound together by the EPS (Fig. 7B) and defined as a microbially derived sessile community characterized by cells that are irreversibly attached to a substratum, interface or to each other, and are embedded in a matrix of EPS that they have produced (Donlan and Costerton, 2002). The ability of such bacteria to adhere to surfaces is a critical first step in biofilm formation and how they adhere is discussed in detail below. Once bacteria have adhered to a surface they accumulate and form biofilms with the production of EPS by the sessile bacteria (Fig. 7). Bacterial EPS is composed of polysaccharides, proteins and/or extracellular DNA (eDNA), and similar to capsule composition, EPS components and the amount produced varies between and within species (Donlan and Costerton, 2002). Biofilm formation has been implicated as the cause of chronic and persistent infection in a variety of diseases as highlighted in Table 3. Once a biofilm has formed, the biofilm facilitates resistance against the host's immune system response (Sabate Bresco et al., 2017) and confers antibiotic resistance as the antibiotics cannot penetrate the biofilm effectively (Donlan and Costerton, 2002; Mack et al., 2006). Biofilm formation also complicates medical and surgical treatment protocols as implant removal is often required to eradicate the biofilm. Further information on biofilm formation by staphylococci and streptococci and its implication in the pathogenesis of these bacteria can be found in (Geoghegan and Speziale, 2015).

The antigenic properties of the capsular polysaccharide have been used as targets in the development of vaccines against clinical bacteria such as *Strep. pneumoniae* (Geno et al., 2015) and *Haemophilus influenzae* type B (Giesker and Hensel, 2014). However due to the lack of immunogenicity in young children and the elderly, polysaccharide vaccines have been conjugated to a carrier protein (glycoconjugated vaccine) to stimulate an immune response against bacteria that cause meningitis and pneumonia (De Gregorio et al., 2013; Murray et al., 2015). Vaccines against bacteria that form biofilms such as *S. epidermidis*, *S. aureus* and *P. aeruginosa* have been researched for years (McKenney et al., 2000; Tümmler, 2019), but there are no licensed vaccines at present against such bacteria, mainly because of the variation in the expression of the targeted EPS molecules and failure to show efficacy in clinical trials (Moriarty et al., 2016; Tümmler, 2019).

Table 3 Bacteria commonly associated with biofilm-related infections.

Biofilm-related infection	Bacteria species
Cystic fibrosis lung infection	<i>S. aureus</i> , <i>Haemophilus influenzae</i> , <i>P. aeruginosa</i> , <i>Klebsiella pneumoniae</i>
Central venous catheter	<i>S. aureus</i> , <i>P. aeruginosa</i> , <i>K. pneumoniae</i> , <i>Enterococcus faecalis</i>
In-dwelling urinary catheter	<i>Staphylococcus epidermidis</i> , <i>Enter. faecalis</i> , <i>E. coli</i> , <i>Proteus mirabilis</i> , <i>P. aeruginosa</i> , <i>K. pneumoniae</i> , <i>Enterobacter aerogenes</i>
Contact lens	<i>P. aeruginosa</i> , <i>S. aureus</i> , <i>S. epidermidis</i> , <i>E. coli</i> , <i>Serratia</i> spp., <i>Proteus</i> spp.
Chronic wound	<i>Staphylococcus</i> spp., <i>Pseudomonas</i> spp., <i>Enterobacter</i> spp., <i>Stenotrophomonas</i> spp., <i>Proteus</i> spp., <i>Morganella</i> spp., <i>Serratia</i> spp.
Orthopaedic device related infections	<i>S. epidermidis</i> , <i>S. aureus</i> , coagulase negative staphylococcus (CoNS), <i>Propionibacterium acnes</i> , <i>E. coli</i> , <i>P. aeruginosa</i> , Non- <i>E. coli</i> Enterobacteriaceae, <i>Enterococcus</i> spp., <i>Streptococcus</i> spp.
Endocarditis	<i>Streptococci</i> (including viridans streptococci, enterococci, pneumococci, and <i>Streptococcus bovis</i>), <i>S. aureus</i> , CoNS including <i>S. epidermidis</i>
Otitis media (middle ear infection)	<i>Strep. pneumoniae</i> , <i>H. influenzae</i> , <i>Moraxella catarrhalis</i> , group A beta-hemolytic streptococci, enteric bacteria, <i>S. aureus</i> , <i>S. epidermidis</i> , <i>P. aeruginosa</i>

Flagella

Many bacteria are motile by swimming due to structures called flagella (flagellum singular) and found on Gram-negative and -positive bacteria. Flagella are long, thin helical shaped appendages that are anchored to the bacterium in the cytoplasmic membrane and cell wall and a rope-like filament protruding out of the cell wall (Fig. 8; Murray et al., 2015). Depending on the species, a bacterium can have one or several flagella on their cell surface. In rod shaped bacteria, flagella can be attached at one or both ends of the cell (polar flagella), or several can arise like a tuft at one end of the cell (lophotrichous flagella), or they can be inserted at many locations along or around the cell (peritrichous flagella) (Fig. 8; Madigan et al., 2019). The latter is commonly seen in motile coccus shaped bacteria. Flagella type is also used in the classification of bacteria.

The flagellum is composed of several components (Fig. 8) and like a tiny motor, propels the bacteria towards nutrients and away from harmful compounds (chemotaxis). The basal body comprised of multiple ring-like subunits anchors and powers the flagella, the hook connects the filament to the basal body, and the filament extends out of the cell (Fig. 8). The filament is composed of multiple subunits of the protein flagellin, which to some extent determines the structure and shape of the filament, and the rotation direction (Aizawa, 2015). Flagella rotate in an anticlockwise or clockwise direction, but not at a constant speed, rather they increase and decrease their rotational speed as needed. Depending on the number of flagella and their location on the cell surface the bacteria can move in a linear direction or tumble (Aizawa, 2015). Bacteria with peritrichous flagella tend to move slowly in a straight line, while polar flagella allow the bacteria to move rapidly, tumbling or spinning around in a zig zag motion (Madigan et al., 2019). Swarming motility is also seen in bacteria that are hyperflagellated such as *Proteus* spp. where thousands of flagella

**Fig. 8** Flagellum in Gram-negative bacteria (A) structure of flagellum, and (B) different flagella arrangement.

propel the bacteria forwards in a smooth motion (Aizawa, 2015). Motility is an important virulence factor for many bacteria as the flagella not only allows the bacteria to move but also expresses antigenic properties that activate innate immune responses (Aizawa, 2015; Murray et al., 2015).

Fimbriae and pili/fibrils

Fimbriae and pili are small hair-like filamentous protein appendages that extend from the bacterial cell surface of Gram-negative and -positive bacteria (Fig. 3). Fimbriae are morphologically distinct from flagella as they are much shorter, with smaller diameters, straighter without the curved spiral structure of flagella, and are much more numerous on the cell surface (Murray et al., 2015). Multiple types of fimbriae exist, and their functions are varied. One of the first roles associated with pili was in facilitating genetic exchange between bacteria as sex pili confer the ability to bind to other bacteria and initiate the process of conjugation, and they also function as receptors for bacteriophages (Barer, 2018). In pathogenic Gram-negative bacteria such as *E. coli* (UTIs, gastrointestinal infections), *Salmonella* spp. (salmonellosis, food poisoning), *Neisseria gonorrhoeae* (gonorrhoea) and *Bordetella pertussis* (whooping cough) fimbriae promote adherence and/or invasion to host tissues (Lukaszczuk et al., 2019), while in *E. coli* and Gram-positive bacteria such as *Staphylococcus* spp. and *Streptococcus* spp., curli amyloid fibrils are associated with adhesion and biofilm formation (Volkan et al., 2015). Pili are longer in length, and Type IV pili are found in various Gram-negative bacteria such as *P. aeruginosa*, *N. gonorrhoeae*, *Neisseria meningitidis*, and *Vibrio cholerae* (cholera), as they assist in adhesion but are also involved in twitching motility (Lukaszczuk et al., 2019). In twitching motility, the pili are found on the poles of rod shaped bacteria and by extending and retracting, drag the cell across a surface in a gliding-like motion, thus Type IV pili have been implicated as important in the colonization of bacteria such as *N. gonorrhoeae* and *V. cholerae* as they assist the bacteria in finding suitable adhesion sites for the bacteria to initiate an infection (Madigan et al., 2019). As mentioned above, Type IV pili also have a role in the transfer of DNA into other cells via conjugation.

Other virulence factors

Cell wall associated proteins in Gram-positive pathogens

Pathogenic Gram-positive cocci such as *Staphylococci* and *Streptococci* express a variety of virulence factors on their cell wall, including surface proteins, that are covalently bound to the cell wall peptidoglycan (Fig. 6; Nobbs et al., 2009; Foster, 2019). These cell wall associated (CWA) proteins have an important role in adhesion, colonization of host tissues and evasion of host defences.
